Abstract. Tubular halloysite and microfibrous palygorskite clay mineral combined with nanocrystalline TiO$_2$ are involved in the preparation of nanocomposite films on glass substrates via sol-gel route at 450°C. The synthesis employing nonionic surfactant molecule as pore directing agent along with the acetic acid-based sol-gel route without addition of water molecules. Drying and thermal treatment of composite films ensure elimination of organic material lead to the formation of TiO$_2$ nanoparticles homogeneously distributed on the palygorskite and halloysite surfaces. Nanocomposite films without cracks of active anatase crystal phase on palygorskite and halloysite surfaces are characterized by microscopy techniques, UV-Vis spectroscopy, and porosimetry methods in order to examine their structural properties. The composite palygorskite-TiO$_2$ and halloysite/TiO$_2$ films with variable quantities of palygorskite and halloysite were tested as photocatalysts in the photo-oxidation of Basic Blue 41 azo dye in water. These nanocomposite films proved to be most promising photocatalysis and highly effective to dye’s decoloration in spite of small amount of palygorskite/TiO$_2$ or halloysite/TiO$_2$ catalyst immobilized onto glass substrates.

INTRODUCTION

Nowadays water pollution has become one of the most serious problems worldwide. A variety of organic and inorganic pollutants produced by anthropogenic activities affect water quality and in some cases render water a rare element for consumption by humans. Degradation of various organic pollutants by photocatalysis, using wide band gap semiconductors under UV or solar light, has been extensively studied [1-3]. In the case of organic pollutants, azo dyes are being used in huge quantities for example in the textile industry. The presence of dye in the wastewater of the textile industry affects the photosynthetic process and generates toxicity to the aquatic organisms and also humans [4-6]. The use of highly porous materials such as clay minerals can be considered as alternative substrates for TiO$_2$ immobilized particles [7-8]. Halloysite clay mineral with tubular structure could be considered as suitable and also cheap material for TiO$_2$ particles immobilization [9-10]. In addition palygorskite clay mineral microfibers combined with TiO$_2$ have been used for the decomposition of NO$_x$ gases and toluene [11-12].

In this work we present the fabrication of thin mesoporous nanocrystalline TiO$_2$ composite films with halloysite and palygorskite clay minerals. The enhanced photocatalytic activity of TiO$_2$ nanoparticles in combination with halloysite nano tubes and palygorskite microfibers was examined to the discoloration of azo-dye Basic Blue 41 in aqueous solutions.

MATERIALS SYNTHESIS AND CHARACTERIZATION

Commercially available Triton X-100 (X100, polyethylene glycol tert-octylphenyl ether), titanium tetraisopropoxide (TTIP), acetic acid (AcOH), Basic Blue 41 (BB-41) and all solvents were purchased from Sigma-Aldrich. Double distilled water with resistivity 18.2 MΩ (Miliqore) was used in all experiments. Palygorskite-rich samples (PAL) from Ventzia continental basin, Western Macedonia Greece. Pure and well crystalline halloysite samples (HAL) with tubular morphology were originated from Utah, USA. A amount of X100 was homogeneously dissolved in ethanol (EtOH). Titania precursor, TTIP was added at a time under vigorous stirring. The molar ratio of the materials was optimized at X100:EtOH:AcOH:TTIP=1:69:6:1 in accordance to previous results [13-14].
Palygorskite powder was mixed with previous solution in various quantities following PAL weight ratio 0%, 33%, 50%, 65%, 75% compared to TiO₂. Films prepared on glass slides for the five PAL-TiO₂ weight ratios will be referred as PAL0, PAL33, PAL50, PAL65 and PAL75 respectively. In addition, halloysite powder was mixed with previous solution in various quantities following HAL 5%, 20%, 25% and 30% weight ratio compared to TiO₂. Samples, abbreviated as HAL5, HAL20, HAL25 and HAL30, while HAL0 is referred to pure TiO₂ films. After several minutes, the dispersion was ready to be used on glass slides. Films prepared on glass slides for the four HAL weight ratios will be referred as HAL5, HAL20, HAL25 and HAL30 respectively while HAL0 represents pure TiO₂ films without the presence of halloysite.

A Bruker D8 Advance diffractometer with CuKα (λ = 1.5406 Å) radiation and Bragg-Brentano geometry was employed for X-ray diffraction (XRD) studies of the PAL-TiO₂ and HAL-TiO₂ catalyst. The XRD patterns showed the halloysite, palygorskite and TiO₂ anatase peaks. Nitrogen intrusion/extrusion curves were measured with a Micromeritics Tristar 3000 and the surface area, porosity, and pore size distribution were derived by differentiating them according to BET method for the HAL-TiO₂ (Table 1).

However, Hg porosimetry measurements were performed for PAL-TiO₂, instead of BET measurements that are, usually, used for the characterization of titania films. Hg porosimetry measurements are performed in order to obtain...
information for pore sizes larger than 0.5 μm, which are not attainable by gas sorption. For porosity measurements, the mercury intrusion curves of all samples were taken with a Quantachrome PoreMaster 60 Mercury Porosimeter while the surface area, porosity, and pore size distribution were derived by curves’ differentiation (Table 1). For the visual morphology of PAL-TiO₂ and HAL-TiO₂ nanostructure, an environmental scanning electron microscope (FESEM, Zeiss SUPRA 35VP) was used and inspect film homogeneity [Fig. 1 (a)-(d)]. Absorption measurements of BB-41 sols were carried out with a Hitachi U-2900 UV-Vis spectrophotometer.

In both HAL-TiO₂ and PAL-TiO₂ nanocomposites decomposition kinetics of BB-41 has been observed to follow first-order kinetics and it is well established that photo-discoloration experiments follow Langmuir-Hinshelwood model, where the reaction rate, \( r \), is proportional to the surface coverage, \( \theta \), according to the following equation 1 [15]:

\[
\frac{dC}{dt} = k_1 \theta = \frac{k_1 K C}{1 + K C}
\]

where \( k_1 \) is the reaction rate constant, \( K \) is the adsorption coefficient of the reactant and \( C \) is the reactant concentration. In the case that \( C \) is very small, \( K C \) factor is negligible in respect to unity and the above equation describes first-order kinetics. The integration of the above equation yields to the following equation 2:

\[
- \ln\left(\frac{C}{C_0}\right) = k_{app} t
\]

With limit condition that on \( t=0 \) we have the initial concentration \( C_0 \), \( k_{app} \) is the apparent first-order rate constant.

![Figure 2](image)

**FIGURE 2.** (a) Photo-discoloration of BB-41 by TiO₂ films in presence of different weight percentages of halloysite under UV light. (b) Photodecoloration of BB-41 by different PAL-TiO₂ catalysts. S1, S2, S3 and S4 refer to PAL33, PAL50, PAL65 and PAL75 respectively.

In the case of HAL20 a complete decolorization was reached within 140 min of illumination implied the synergistic effect between clay mineral and TiO₂ by preparing highly porous HAL-TiO₂ catalysts [Fig. 2(a)]. In the case of PAL65 a complete discolorization was reached within 90 min of illumination implied the synergistic effect between palygorskite and TiO₂ by preparing highly porous PAL-TiO₂ catalysts. However, the further addition of palygorskite in films (PAL75) caused a slight decrease on the photocatalytic activity of films [Fig. 2(b)].

![Figure 3](image)

**FIGURE 3.** Ln(C₀/C) as a function of irradiation time for: (a) HAL-TiO₂ and (b) PAL-TiO₂ photocatalysts. S1, S2, S3 and S4 refer to PAL33, PAL50, PAL65 and PAL75 respectively.

Discoloration kinetics of BB-41 in presence of different HAL proportions in TiO₂ nanocrystalline films is presented in Fig. 3(a). The maximum value for rate constant was calculated for sample HAL20 (29.8x10⁻³ min⁻¹) while the value for pure TiO₂ film was estimated at 12.9x10⁻³ min⁻¹. Furthermore, all the samples HAL-TiO₂ exhibited better performance than pure TiO₂. We mainly attribute this behavior to the internal light scattering because of the presence of the halloysite. In addition discoloration kinetics of BB-41 in presence of different PAL/TiO₂ proportions is presented in Fig. 3(b). The maximum value for rate constant was calculated for sample PAL65 (38x10⁻³ min⁻¹) while the value for pure TiO₂ film was estimated at 18x10⁻³ min⁻¹. Furthermore, all the
samples PAL/TiO₂ exhibited better performance than pure TiO₂. This is attributed to better structural characteristics of the films compared to pure titania film tabulated at porosity and particle surface area.

The above findings for the HAL-TiO₂ and PAL-TiO₂ nanocomposites could be also attributed to better structural characteristics of the films compared to pure TiO₂ film mainly tabulated at porosity and total pore volume. However, the rate of dye discolorization depends on adsorption of the dye into the catalyst porous structure. Finally, it has been found that the same photocatalysts can be used in several photocatalytic cycles without remarkable loss to their efficiency.

CONCLUSIONS

Both the HAL-TiO₂ and PAL-TiO₂ films exhibited enhanced structural properties including crystallinity and active anatase phase, while enhanced photocatalytic properties to the discoloration of BB-41 in water were succeeded. The experiments on photocatalytic discoloration of BB-41 indicated the importance of preparing highly porous HAL- TiO₂ and PAL-TiO₂ films where a synergistic effect between halloysite tubes and palygorskite microfibers with the TiO₂ nanoparticles could be occurred.
