Thus study is reported according to the STROBE statement for observational studies.
ABSTRACT

Background
Chronic rhinosinusitis (CRS) is a common and debilitating disorder. Little is known about the epidemiology of this disease. The aims of the study were to identify differences in socio-economic variables and quality of life between patients with chronic rhinosinusitis and healthy controls, to identify any significant associations between CRS and other medical co-morbidities, psychiatric disease or environmental exposure and to explore the experience of CRS from the perspective of CRS sufferers.

Methods
Participants were recruited from ENT clinics from 30 centres across the UK. They completed a study-specific questionnaire considering environmental, medical and socio-economic factors, and SF-36 and SNOT-22 scores. All participants with CRS were diagnosed by a clinician and categorised as having CRS (with polyposis, without polyposis or allergic fungal rhinosinusitis (AFRS)). Controls included family and friends of those attending ENT outpatient clinics and hospital staff who had no diagnosis of nose or sinus problems and had not been admitted to hospital in the previous 12 months.

Results
A total of 1470 study participants (1249 patients and 221 controls) were included in the final analysis. Highly significant differences were seen in generic and disease-specific quality of life scores between CRS sufferers and controls; mean SNOT-22 score 45.0 for CRS compared with 12.1 amongst controls (p<0.001). There were no clear differences in socioeconomic variables including, social class, index of multiple deprivation and educational attainment between cases and controls. Common comorbidities with a clear association included respiratory and psychiatric disorders (p ≤ .0001), with a higher frequency of reported upper respiratory tract infections.

Conclusions
CRS is associated with significant impairment in quality of life and with associated medical co-morbidities. In contrast to other common ENT disorders, no socioeconomic differences in CRS were found between patients and controls in this study.
INTRODUCTION

Background and rationale

Chronic rhinosinusitis (CRS) affects a significant proportion of the population; a recent European study found a prevalence of 11%\(^{(1)}\). Despite this, the epidemiology of CRS and in particular its association with socioeconomic variables has not been extensively explored. The European Position Paper on Rhinosinusitis and Nasal Polyps (EPOS 2012) has stated under the heading ‘Research Needs’ that studies are required to consider ‘the prevalence of and predisposing factors for CRSSNPs and CRSwNPs’ and to ‘investigate the impact of psychological problems such as depression, stress exposure and anxiety on subjective severity’\(^{(2)}\). A previous study of 158 patients has suggested significant morbidity in CRS with quality of life scores worse than amongst those with other chronic diseases such as lower back pain\(^{(3)}\). This significant effect on an individual’s functioning and productivity, since CRS primarily affects those aged 40-60 years, has an impact upon workforce productivity. CRS has been identified as one of the top ten most costly diseases for US employers \(^{(4)}\). Despite its high prevalence and impact, the pathophysiology and hence optimal treatment for CRS are not well understood, but it is thought to be a spectrum of diseases with different underlying aetiologies and pathological features. Infection (viral, bacterial and fungal) and underlying genetic tendencies may all be contributory factors. CRS is currently subdivided into two main types – CRS with and without nasal polyps (CRSwNPs and CRSSNPs respectively), as exemplified by EPOS 2012\(^{(2)}\) to reflect coarsely differing gross pathophysiology (eosinophilic or neutrophilic) but allergic fungal rhinosinusitis (AFRS) is an increasingly recognised distinct subtype of CRSwNPs.

Deprivation is known to be associated with increasing morbidity and mortality, and is therefore important to consider in understanding the epidemiology of any disease, since it is a potentially reversible determinant of health \(^{(5)}\). Many reasons for this relationship have been explored. Poor nutrition leads to poor mental and physical development. Cold or damp housing is associated with increased risk of respiratory diseases, and overcrowded housing is associated with infectious diseases \(^{(6)}\). Behavioural differences which may be related to lack of resources or poor education also contribute to socioeconomic variation in health, with smoking being the most common example. Reduced access to health care, genetic factors and adverse social conditions also contribute \(^{(7)}\). Within otorhinolaryngology it is known that
one of the most common risk factors for otitis media is socioeconomic status \(^{(8)}\), with more deprived children more likely to suffer adversely with the condition. There is controversy as to the role of deprivation in other upper respiratory problems; the direction of association between asthma and socioeconomic status varies widely between studies \(^{(9)}\) \(^{(10)}\).

By developing our understanding about the socio-economic and co-morbidity factors that may influence CRS, specific co-morbid associations and high-risk population groups might be identified. This information could enable health practitioners, including ENT specialists and General Practitioners, to better tailor management to individual patients’ needs.

Epidemiological studies outwith Europe have shown varying prevalence rates. In Canada, the prevalence of CRS, defined as an confirmatory answer to the question, ‘Has the patient had sinusitis diagnosed by a health professional lasting for more than 6 months?’ ranged from 3.4% in male to 5.7% in female subjects \(^{(11)}\). In Korea, the overall prevalence of CRS, defined as the presence of at least 3 nasal symptoms persisting for more than 3 months, together with an endoscopic finding of nasal polyps and/or mucopurulent discharge within the middle meatus, was 1.01% \(^{(12)}\). A comparative study between the north of Scotland and the Caribbean found that in ENT clinics across both countries, there was a similar prevalence of CRS (9.6% and 9.3% respectively \(^{(13)}\).

**Objectives**

To date no large scale study into the epidemiology of CRS has been undertaken in the UK and the Chronic Rhinosinusitis Epidemiology Study (CRES) meets this need. The primary aim of the study was to identify differences in socio-economic variables and quality of life between patients with chronic rhinosinusitis and healthy controls. Secondary aims were to identify any significant associations between CRS and other medical co-morbidities, psychiatric disease or environmental exposure and to explore the experience of CRS from the perspective of CRS sufferers.
MATERIALS AND METHODS

Study Design and Setting
CRES was approved by the Oxford C Research Ethics Committee, sponsored by the University of East Anglia (UEA) and funded by the Anthony Long and Bernice Bibby Trusts. The study was conducted as a prospective case-control questionnaire study. Following a pilot study of the questionnaire in 2006, the study commenced recruitment in ENT departments of the East Anglia region (East of England Deanery) of the UK in 2007. Following elevation to the National Institute of Health Research Clinical Research Network Portfolio in 2012, a total of 30 sites from around the UK (including the devolved nations of Wales and Scotland) joined the study which ran between 2007 and 2013. The study specific questionnaire was anonymous and therefore consent was implied through participation. Participant information leaflets were provided. Questionnaires were completed on one occasion only either before leaving the clinic or taken home and returned by post in Freepost envelopes. A qualitative arm of the study was undertaken in 2012. This is published elsewhere.14, 15

Participants
The diagnosis of CRS was confirmed by an Otorhinolaryngologist. CRS patients presenting to secondary care ENT outpatient clinics were invited to participate in the study, regardless of symptom or disease severity or previous treatment, provided they conformed to the following criteria:

Inclusion criteria: CRS with or without polyps as defined by the criteria laid out in EPOS 2012(2). Symptoms must be present for at least 12 weeks and include:
- nasal blockage/obstruction/congestion and/or nasal discharge (anterior/posterior nasal drip)
- and either facial pain/pressure and/or reduction or loss of smell
and additionally:
- endoscopic signs of: polyps and/or mucopurulent discharge primarily from middle meatus and/or; oedema/mucosal obstruction primarily in middle meatus
- and/or CT changes: mucosal changes within the ostiomeatal complex and/or sinuses
Any patients with nasal polyps placed in the AFRS category met the Bent and Kuhn criteria (16) or the St Paul’s Sinus Centre modification of this (17).

Patients and controls included were at least 18 years of age.

Exclusion criteria:
• Patients unable to comprehend written English.

For the control group:
• patients with active sinonasal disease - e.g. acute or chronic forms of rhinitis/rhinosinusitis (as determined by patient history or SNOT-22 score of 10 or more
• no medical co-morbidity (no chronic medical conditions being actively treated)
• hospitalisation within the last 12 months

Controls included family and friends of those attending ENT outpatient clinics and hospital staff.

Variables and data sources
The study questionnaire was designed with the input of the East of England Research Design Service and included study specific questions relating to socio-economic, environmental and medical co-morbid variables as well as the validated Short Form 36 Quality of Life (QoL) measure (SF-36) (18) measure and the Sino-Nasal Outcome Test questionnaire (SNOT-22) (19).

Socioeconomic variables:
Respondents were asked to enter data for occupation, highest academic qualification, rural/urban location, duration of residency, proximity to crops, postcode, annual income, ethnicity and household occupancy. Social class based on the National Statistics Socioeconomic Classification (NS-SEC) (20) and the Index of Multiple Deprivation (21) were calculated and used to assess socio-economic differences. Participants were also asked about tobacco and alcohol consumption.

Medical Co-morbidities:
Data requested under this category included information on psychiatric disorders, frequency of common respiratory illnesses, past medical and surgical history, drug history, known and suspected allergies and sensitivities to aspirin and foods high in salicylate content.
Sample size calculation

The purpose of the study was to look for common associations between CRS, and primarily social class (as determined by occupation, highest qualification and household income), and CRS and housing status (as determined by occupancy of household in conjunction with social class). These two factors have been used to determine the size of the study sample required.

For socio-economic scores, the standard approach is to compare the proportion of subjects in the lower social classes to everyone else. In order for the study to have 80% power to detect a difference of 10% in "low social class" between controls and CRS patients, assuming a 30% rate in the CRS patients, with approximately 5 CRS patients to 1 control patient, 965 CRS patients and 193 controls were required.

For the purposes of assessing QoL, assuming that a change in QoL of 10 units on SF-36 can be shown (standard deviation of 20), then to have 80% power to detect this difference (at the 5% level of significance), 38 controls and 190 cases would be needed. This would need to be increased by 20% to allow for the non-normality of QoL and the study would need 46 controls and 228 cases.

RESULTS

Participants

A total of 1470 participants with an age range of 17-102 years were recruited. Following adoption on to the NIHR portfolio, recruitment rates improved to a peak of 120 subjects per month. After adoption, the overall recruitment was 66% of those invited to participate. Participants who were recruited prior to adoption onto the portfolio make up the additional participants. Information on recruitment rates prior to adoption was not collected and there is no information on reasons for non-participation. A total of 1535 questionnaires were returned, reduced to 1470 eligible after checking for duplicates and missing information. See figure 1 for participant flow.

Descriptive and outcome data

The 1470 participants included 709 males and 606 females (155 undeclared); 44% had CRSsNPs and 56% had CRSwNPs or AFRS. As demonstrated in figure 2, the geographic distribution of study participants includes a wide range of rural and urban areas of the country and in 3 out of the 4 devolved nations. Table 1 shows detailed demographic information for each of the included
subgroups. The full amount of data available was used for each relevant analysis; for example, if SNOT-22 was completed but not SF-36, participants were included in SNOT-22 analysis but not SF-36. Similarly, for all socioeconomic factors all participants who completed the relevant question were included in that particular analysis, to maximize use of the available data.

Main results

Socio-economic outcomes

Social class is an individual-level assessment based on self-reported occupation: 1350 respondents (91.8%) provided this information. Due to the small number of individuals in some categories, classes 1.1 and 1.2 were combined, 4 and 5 were combined, and 7 and 8 were combined to assess differences. There was a significant association between social class and CRS status (p=0.002); however when adjusted for age and sex the difference was no longer statistical significant (p=0.0684) and there was no specific direction of association.

The index of multiple deprivation (IMD) was also calculated as a measure of socioeconomic status \(^{(21)}\). This is an area-based deprivation measure based on postcode. IMD scores for each postcode are based on government statistics measuring relative levels of deprivation in small areas of England called Lower Layer Super Output Areas (LSOAs). Domains include income, employment, health and disability, education, skills and training, barriers to housing and services, living environment and crime. Most of the indicators used in these statistics are from 2008. There were no significant differences between those with CRS and controls (p=0.115); nor did any appear after adjusting for age and sex (mean difference -1.36, 95% CI: -3.00 to 0.29, p=0.107).

The number of occupants in the household of the participant was also considered; households of controls tended to have more occupants than households of those with CRS (p=0.003), however this was not significant after adjusting for age and sex (p=0.275). Household income (according to the participant) was intended to be used as a further socioeconomic measure but only two thirds of respondents provided information although no significant differences were found. Mean income was £41,118.63 for controls and £42,800.02 for those with CRS. This highest educational qualification achieved by the participant showed no significant differences between controls and those with CRS (p=0.599).
Quality of Life

Quality of life was measured using the SF-36 and SNOT-22. There was a statistically significant association between SNOT-22 and social class but only a weak correlation was detected (Spearman rho = 0.0935, p=0.001). There was no correlation between SNOT-22 score and IMD, number of household occupants or educational attainment. There were statistically significant associations between three socioeconomic variables and SF-36 but all correlations were weak. Results are shown in table 2. There were significant differences in mean scores between controls and those with CRS for both the SF-36 and SNOT-22, before and after adjustment for age and gender differences. Controls had better scores for both scales as illustrated in table 3. A further detailed analysis of the SNOT-22 subscales and differences between CRS subtypes will be reported separately.

Co-morbidities

Several co-morbidities were higher amongst those with CRS than controls, including psychiatric problems (p=0.001) and respiratory.

CRS and Mood disturbances

Chi-squared test showed significant differences between participant subgroups for both depression p=0.03 and anxiety p=0.04 and between mental health domain scores on SF-36 (p=0.05).

Allergies

Those with CRS were more likely to report respiratory tract sensitivity to aspirin (p= 0.003), wine (p<0.001), fruits (0.034) and nuts (0.026), but not to spicy food, drinks or vegetables. Further analysis is required for the free text answers regarding inhalant allergies and will be reported elsewhere.

Respiratory

Asthma had a strong association with CRS (<0.001) with those in the AFRS subgroup most frequently affected. Those with CRS were more likely to report suffering from upper respiratory tract infections (URTIs) ‘often’ OR=7.39 (95% Confidence interval [CI]: 3.31-16.51) or ‘frequently’ 30.25 (95% CI 9.77, 93.63).

Burden of surgery

Amongst all CRS patients, 45% had undergone some form of sinonasal surgery previously (defined as one or more of polypectomy, endoscopic sinus surgery (ESS), septoplasty,
turbinate surgery, rhinoplasty) including 325 (26%) who had received at least one nasal polypectomy and 169 (14%) who had undergone at least one instance of ESS (separately or concurrently). The mean number of previous surgeries per patient in those who had undergone multiple procedures was 3.3 (range 2–30) and a mean duration of time of 10 years since the last procedure. A detailed analysis of the surgical data is reported elsewhere (22).

Lifestyle and Environmental Exposure
There were no significant differences in smoking or alcohol consumption between controls and those with CRS. Nor were there significant differences in proportions of those living near crops between those with CRS and controls. Data on air pollution for all recruitment sites is currently being sought and will be reported separately.

DISCUSSION

Key Results
Sufficient data on socioeconomic status were collected to enable the primary objectives to be determined. There were no significant differences in socio-economic variables as measured by social class, IMD or household occupancy between those with and without CRS. There have been few previous studies investigating the association between CRS and different measures of socioeconomic status, particularly in the UK. A similar sized epidemiological study of residents of Sao Paulo also found no statistically significant differences in CRS prevalence according to number of household residents, educational achievement or income of head of household, but did find a significant association between presence of CRS and belonging to a low-income group (23), although it is noted that social structure in Sao Paulo is different to the UK. Another study of 127 patients found that lower family income was related to worse self-reported sinus disease (although there was no difference in objective sinus disease based on Lund-Mackay score) (24). A study considering markers of disease severity amongst 93 patients with AFRS in North Carolina, found that bone erosion and orbitocranial involvement were associated with lower income, rural counties, poor housing quality, and less health care access (25). Some studies have found that comparable chronic diseases such as asthma have a strong association between poverty and
disease severity\textsuperscript{(10)} but this is controversial\textsuperscript{(9)}. Our study found no differences in education attainment between cases and controls.

There were weak but statistically significant associations between SNOT-22 score and social class, and SF-36 score and social class, household occupancy and educational attainment. Although there is sparse literature investigating such associations amongst those with CRS, Kilty et al found that those with a lower educational level scored more highly on a sinus symptom score\textsuperscript{(24)}.

Highly significant differences were seen in generic and disease-specific QoL scores between cases and controls, with cases having less favourable scores on both SF-36 and SNOT-22, emphasising that CRS patients have a significant impairment of their QoL. This is supported by several previous studies\textsuperscript{(26)}. Potential explanations for the association between socioeconomic variables and disease severity are likely to be multi-factorial, reflecting the wide range of influencing aetiological factors in CRS as well as individuals’ perceptions of symptoms. Several co-morbidities were significantly more likely to be found amongst those with CRS than controls, including psychiatric problems including mood disturbances and asthma. Studies considering the biopathophysiological mechanisms which could be involved in the association between socioeconomic status and the development of asthma have proposed family stress and endotoxin exposure in low-income households as a factor in development and experience of symptoms\textsuperscript{(10)}. For example, caregiver stress in early life has been associated with increased levels of TNF-a in infants, which is known to be a pro-inflammatory cytokine in asthma\textsuperscript{(27)}.

The proportion of those reporting allergies including aspirin, wine, fruits and nuts was higher amongst cases and controls. This is supported by several previous studies\textsuperscript{(28)}.

There were no significant differences in smoking habits or alcohol intake between cases and controls. Existing literature varies as to the nature of any association with CRS. Despite being known to reduce mucociliary clearance time, the association between smoking and CRS varies between studies\textsuperscript{(28, 29)}. A large epidemiological study of over 73,000 Canadians found no association between self-reported smoking and CRS; our study supports this finding\textsuperscript{(11)}. Similarly no association between alcohol intake and CRS was found\textsuperscript{(11)}. Smoking is associated with poorer postoperative outcomes\textsuperscript{(30)}. 
Strengths and Limitations

This study includes a varied population from across the United Kingdom. It is the largest study of CRS in the UK to date. Adoption onto the NIHR portfolio facilitated recruitment and many sites had excellent participation rates. Participants were recruited regardless of previous and subsequent management so there was no bias towards surgical or medical treatment. There should be no difference or bias regarding reporting of socioeconomic factors between controls and those with CRS.

The study design had some limitations; it was a self-reported study which predisposes to recall bias. Only those in secondary or tertiary care were included, although many of those with CRS are exclusively treated in primary care. There were large amounts of missing data for some socioeconomic parameters. If the study was redesigned, controls may have been recruited from a wider pool than just from within hospital staff or from amongst non-CRS ENT patients/relatives, to increase recruitment particularly amongst males. An online version of the questionnaire would have also produced a less labour-intensive data processing period at the end of the study.

The study did not intend and cannot provide information about prevalence of CRS in the general population.

Generalisability

Given the scope of the study incorporating a mixture of different sized academic, tertiary and secondary care sites with participants from a range of urban and rural locations around the UK, we believe the study findings are applicable to the wider population of CRS sufferers presenting to ENT departments. However, given a larger burden of CRS patients is managed in a primary care setting, the results may not necessarily apply to the whole of the CRS affected population.

CONCLUSION

Our study is the first study to assess socioeconomic influences in CRS in the UK and found no socioeconomic differences between those with CRS and controls. This finding is significant in furthering our understanding of the epidemiology of CRS. We identified significant differences in health-related QoL reflecting the substantial negative effect of CRS. This increased
morbidity leads to the increased health care utilisation by patients with CRS, for both nasal and non-nasal symptoms, and within both primary and secondary care. Additionally those with CRS were found to have higher respiratory and psychological co-morbidities. The disease burden associated with CRS needs to be considered in both individual patients’ management and when undertaking clinical and epidemiological research into CRS, but also in the context of planning appropriate use of healthcare resources for this common condition.
