Abstract
Enterohaemorrhagic Escherichia coli (EHEC) is a major foodborne pathogen and tightly adheres to human colonic epithelium by forming attaching/effacing lesions. To reach the epithelial surface, EHEC must penetrate the thick mucus layer protecting the colonic epithelium. In this study, we investigated how EHEC interacts with the intestinal mucus layer using mucin-producing LS174T colon carcinoma cells and human colonic mucosal biopsies. The level of EHEC binding and attaching/effacing lesion formation in LS174T cells was higher compared to mucin-deficient colon carcinoma cell lines, and initial adherence was independent of the presence of flagellin, Escherichia coli common pilus, or long polar fimbriae. Although EHEC infection did not affect gene expression of secreted mucins, it resulted in reduced MUC2 glycoprotein levels. This effect was dependent on the catalytic activity of the secreted metalloprotease StcE, which reduced the inner mucus layer and thereby promoted EHEC access and binding to the epithelium in vitro and ex vivo. Given the lack of efficient therapies against EHEC infection, StcE may represent a suitable target for future treatment and prevention strategies.

1 INTRODUCTION

Enterohaemorrhagic Escherichia coli (EHEC) is a major foodborne pathogen in the developed world and affects mainly young children and the elderly (Croxen et al., 2013). Most infections are caused by serotype O157:H7 strains (Gould et al., 2013). In addition to causing diarrhoea and haemorrhagic colitis, EHEC infection can result in life-threatening haemolytic uraemic syndrome (HUS), which is the main cause of acute kidney failure in children in western countries and can lead to lifelong renal and neurological impairment (Trachtmann, Austin, Lewinski, & Stahl, 2012). Notably, there is currently no specific treatment against EHEC infection and HUS, and the use of antibiotics is not recommended due to increased risk of developing HUS (Freedman et al., 2016).

After entering the human gut, EHEC binds to the intestinal epithelium by adhesins such as fimbriae, pili or flagella (McWilliams & Torres, 2014). This initial recognition step is then followed by the formation of firm attaching/effacing (A/E) lesions mediated by a type III secretion system. In particular, the bacterial translocated intimin receptor is injected into the host cell and becomes exposed on the cell membrane. Subsequently, the EHEC outer membrane protein intimin binds to translocated intimin receptor leading to intimate bacterial attachment and initiating further signalling events within the host cell, which ultimately result in actin polymerisation and pedestal formation (Stevens & Frankel, 2014). Although EHEC A/E lesions have not been observed clinically, ex vivo culture of human intestinal biopsies indicates EHEC...
A/E lesion formation in the distal small intestine and colon (Chong et al., 2007; Lewis, Cook, Tighe, & Schüller 2015).

Before adhering to the intestinal epithelium, EHEC must penetrate the mucus layer, which acts as a physicochemical barrier and protects the underlying epithelium from pathogens and foreign antigens. In the colon, the mucus layer is around 400 μm thick and formed of two layers (Johansson et al., 2014; McGuckin, Lindén, Sutton, & Florin 2011). Whereas the inner layer is dense, firmly attached to the epithelium, and virtually free of bacteria, the outer layer is loose, easily penetrable, and densely colonised by the gut microbiota (Johansson et al., 2008). The mucus layer is comprised of mucin glycoproteins secreted by epithelial goblet cells (McGuckin et al., 2011). Around 20 mucins have been identified so far with the majority bound to the cell surface forming the glycocalyx. In contrast, gel-forming mucin glycoproteins are secreted from goblet cell granules and oligomerize into complex macromolecular structures incorporating water and thereby forming the inner and outer mucus layer (Juge, 2012; McGuckin et al., 2011). In the human intestine, MUC2 is the major secreted mucin of the mucus layer (Johansson et al., 2008).

Although the interaction of EHEC with the intestinal epithelium has been intensely studied, its relationship with the mucus layer remains largely unknown. In this study, we have investigated EHEC binding and its effect on the mucus layer in mucus-producing human intestinal epithelial cell lines and mucosal biopsy samples.

2 | RESULTS

2.1 | EHEC adherence to mucus-producing and mucus-deficient intestinal epithelial cells

To determine EHEC binding to different colon carcinoma cell lines, colonocyte-derived HT-29 and Caco-2 and goblet cell-derived LS174T cells were chosen. As shown in Figure 1a, only LS174T cells produced MUC2, whereas no specific staining could be detected for HT-29 and Caco-2 cells. Interestingly, binding of all EHEC strains tested (TUV 93-0, 85-170, and Sakai) was significantly higher in LS174T cells compared to Caco-2 and HT-29 cells after 1 hr of infection (Figure 1b).

We next examined which adhesins were involved in binding to mucus-deficient Caco-2 and mucus-producing LS174T cells. Infections were performed with isogenic EHEC deletion mutants in intimin (Δeae), E. coli common pilus (Δcep), long polar fimbriae (ΔlpfA1), and flagellin (ΔflIC). As no significant differences in binding were detected after 1 hr of infection (Figure S1), the incubation period was prolonged to 3 hr to allow sufficient time for expression of adherence factors. Whereas none of the adhesins tested significantly affected EHEC binding to Caco-2 cells, increased binding to LS174T cells was observed in the absence of flagellin (Figure 2a). In addition, the intimin-negative mutant showed reduced binding to LS174T cells, although this did not reach significance. Subsequent immunofluorescence staining to detect actin pedestals demonstrated EHEC A/E lesions in LS174T but not in Caco-2 cells after 3 hr of infection. As expected, EHEC Δeae did not form A/E lesions in either cell line (Figure 2b). No pedestal formation was observed in LS174T or Caco-2 cells after 1 hr (data not shown), and wild-type EHEC demonstrated actin recruitment in Caco-2 cells after 6 hr of infection (Figure 2b).

2.2 | Influence of EHEC infection on mucus production

In order to determine the effect of EHEC infection on mucus expression, LS174T cells were incubated with EHEC for up to 6 hr, and gene expression of the two major secreted mucins, MUC2 and MUC5AC, was examined by quantitative reverse transcription polymerase chain reaction (qPCR). No significant changes were observed in EHEC-infected versus non-infected cells (Figure 3a). In contrast, immunofluorescence staining demonstrated significantly decreased MUC2 protein levels after EHEC infection (Figure 3b,c). Counterstaining of cell nuclei with 4',6-diamidino-2-phenylindole (DAPI) confirmed that this was not due to cell detachment (Figure 3b). In addition, MUC5AC was only produced by a small subset of cells, and staining intensity was not influenced by EHEC infection (Figure 3d,e).

2.3 | StcE decreases MUC2 protein levels and enhances EHEC binding to colonic epithelium

Previous studies have identified a secreted EHEC metalloprotease (StcE) with mucinase activity for human saliva (Grys, Siegel, Lathem, & Welch, 2005). In order to investigate whether StcE affected intestinal MUC2 levels during EHEC infection, we generated an isogenic stcE

![Figure 1](image)
deletion mutant in strain TUV 93-0 by Lambda Red recombination. As shown in Figure 4a and b, deletion of stcE significantly impaired reduction of MUC2 levels in EHEC-infected LS174T cells. This was restored to wild-type levels after complementation with StcE (Figure 4a,b). In contrast, complementation with catalytically inactive StcE (E447D) did not exhibit any effect, and MUC2 levels were comparable to those of the deletion mutant (Figure 4a,b). In addition to immunofluorescence staining, StcE-dependent MUC2 reduction was confirmed by
sodium dodecyl sulfate (SDS)-agarose gel electrophoresis of cell lysates and subsequent Western blotting with MUC2-specific antibodies (Figure 4c,d). We further determined whether decreased MUC2 levels facilitated EHEC access and binding to the epithelium and quantified the number of total adherent bacteria (binding to mucus layer and epithelium) and bacteria associated with actin pedestals (binding to epithelium only). Whereas similar numbers of wild-type, ΔstcE and complemented EHEC were associated with LS174T monolayers, a significant reduction in actin pedestal formation was observed with the ΔstcE mutant (Figure 4e).

To confirm the effect of StcE on mucus production and EHEC adherence in a biologically relevant model, we performed in vitro organ culture (IVOC) of human colonic biopsy samples (Lewis et al., 2015). Whereas the epithelium was covered by a firmly adherent inner mucus layer in non-infected tissue samples, diminished MUC2 levels and exposure of underlying crypt-associated goblet cells was evident after 8 hr of EHEC infection (Figure 5a,b). In contrast, incubation with EHEC ΔstcE resulted only in marginal disruption of the mucus layer leading to the appearance of “dark holes” devoid of MUC2 staining. Attenuated mucus reduction by EHEC ΔstcE was restored to wild-type levels after complementation with wild-type but not catalytically inactive StcE (Figure 5a,b). To further determine the impact of decreased mucus levels on EHEC adherence to the biopsy epithelium, we removed the mucus layer after the IVOC and quantified adherent EHEC by immunofluorescence staining. As shown in Figure 5c, EHEC bacteria were predominantly attached to the intercrypt surface epithelium, and no adhering bacteria were detected in non-infected control samples. Quantification of adherent bacteria revealed a significant decrease in epithelial binding of EHEC ΔstcE compared to the wild-type and complemented strain (Figure 5d).

3 | DISCUSSION

EHEC is a colonic pathogen which binds tightly to human intestinal epithelium by forming A/E lesions (Lewis et al., 2015). To do so, the bacteria must first interact with and penetrate the thick mucus layer overlying the colonic epithelium (Johansson et al., 2014; McGuckin et al., 2011). How this happens is still largely unknown due to a paucity of suitable animal models (Ritchie, 2014). In addition, most human cell line models used to study EHEC infection (e.g., T84, Caco-2, and HT-29 colon carcinoma cells) are devoid of a MUC2-containing mucus layer (Navabi, McGuckin, & Lindén 2013; van Klinken et al., 1996; Walsham et al., 2016). Using goblet cell-like LS174T colon carcinoma cells which
produce MUC2 glycoproteins (van Klinken et al., 1996), we found that EHEC O157:H7 prototype strains adhered better to this cell line compared to mucus-deficient Caco-2 and HT-29 cells. A similar phenotype has recently been reported for the related A/E pathogen enteropathogenic E. coli, which demonstrated increased binding to LS174T versus HT-29 cells (Walsham et al., 2016). In addition, adhesion of Salmonella enterica to mucus-producing HT-29 MTX cells was significantly increased compared to mucus-deficient HT-29 and Caco-2 cells (Gagnon, Zihler Berner, Chervet, Chassard, & Lacroix, 2013). Although many different adhesins have been identified for EHEC, there is very limited information on EHEC binding to mucus (McWilliams & Torres, 2014). Previous studies have shown binding of EHEC H7 flagella to isolated bovine colonic mucus and mucin from bovine submaxillary glands and porcine stomach (Erdem, Avelino, Xicohtencatl-Cortes, & Girón, 2007). Here, we showed increased adhesion of a fliC EHEC deletion mutant to LS174T cells compared to the wild-type strain. This result may be explained by upregulation of other colonisation factors in the fliC mutant as previously shown for Pseudomonas aeruginosa, where deletion of flagellin resulted in induction of the type III secretion system (Soscia, Hachani, Bernadac, Filloux, & Bleves, 2007). Furthermore, deletion of long polar fimbriae enhanced EHEC adherence to human intestinal explants suggesting cross talk between bacterial adhesion systems (Fitzhenry et al., 2006). Alternatively, the lack of motility associated with these mutants may lead to enhanced binding or retention in the mucus layer (Rossez, Wolfson, Holmes, Gally, & Holden, 2015). It was further noted that EHEC A/E lesion formation in LS174T cells occurred earlier than in Caco-2 cells, thereby explaining the observed dependency on intimin for adherence to this cell line. Whether enhanced EHEC binding and A/E lesion formation in LS174T cells is ultimately linked to mucus production or associated with expression of other cell surface receptors remains to be established. In addition, the role of other EHEC adhesins in binding to human intestinal mucus should be investigated.

In the second part of this study, we investigated the influence of EHEC infection on mucus production. Previous reports on the murine A/E pathogen Citrobacter rodentium demonstrated dynamic changes in mucus thickness during infection (Gustafsson et al., 2013). During the acute phase, mucin expression and goblet cell numbers were reduced...
in the distal colon, and this was dependent on the host adaptive immune response (Bergstrom et al., 2008; Lindén, Florin, & McCuckin, 2008). In contrast, increased mucus secretion at later stages of infection promoted expulsion of bacteria into the gut lumen and clearance of infection (Bergstrom et al., 2010; Gustafsson et al., 2013). The protective role of the mucus layer during Citrobacter infection was further demonstrated by studies in Muc2-deficient mice, which exhibited increased weight loss and mortality due to elevated pathogen burden at the mucosal surface (Bergstrom et al., 2010). Similar to Citrobacter, infection with atypical but not typical enteropathogenic E. coli increased mucus production in rabbit ileal loops and mucin-producing HT-29 MTX cells, which promoted bacterial growth in the absence of luminal flow (Vieira et al., 2010).

Apart from MUC2, LS174T cells also secrete MUC5AC, which is usually expressed in the stomach but also associated with colon cancer (Bartman et al., 1999; van Klinken et al., 1996). In our studies, no changes in MUC2 and MUC5AC gene expression were detected in EHEC-infected LS174T cells. This is in contrast to previous studies demonstrating increased MUC2 gene expression in HT-29 cells infected with EHEC (Xue et al., 2014). This discrepancy is likely related to the difference in cell line models, and as HT-29 cells do not express MUC2 glycoproteins (Huet et al., 1995; Walsham et al., 2016), the relevance of this finding remains questionable.

In contrast to the gene expression results, MUC2 protein levels were significantly decreased in EHEC-infected LS174T cells. This is in agreement with a recent study reporting reduction of the MUC2-containing inner mucus layer in EHEC-infected colonic organoids (In et al., 2016). One likely explanation for this phenotype is the production of mucus-degrading enzymes, which has been reported in enteropathogens (McGuirk et al., 2011). Shigella flexneri and enteroaggregative E. coli secrete the mucin-degrading serine protease Pse (Henderson, Czecezulis, Eslava, Noriega, & Nataro, 1999), and Vibrio cholae produces the mucinolytic metalloproteases Hap and TagA (Silva, Pham, & Benitez, 2003; Szabady, Yanta, Halladin, Schofield, & Welch, 2011). Interestingly, the latter has high sequence homology to the StcE zinc metalloprotease from EHEC, which is located on the pO157 virulence plasmid and secreted by a type II secretion system (Latham et al., 2002). StcE has been shown to modulate the host immune response by cleaving C1 esterase inhibitor and CD43 and CD45 neutrophil glycoproteins (Latham et al., 2002; Szabady, Walters, Huttenlocher, & Welch, 2009) and also reduces the viscosity of human saliva by degrading mucin 7 and glycoprotein 340 (Grys et al., 2005). However, recombinant StcE did not show any activity against purified human MUC2 (Grys, Walters, & Welch, 2006), and infection of human colonic organoids with an stcE mutant only resulted in a slight decrease in mucus reduction compared to the wild-type strain (In et al., 2016). Here, we found that deletion of stcE significantly diminished reduction of mucin levels during EHEC infection of LS174T cells. As catalytic inactivation of StcE had the same effect, it is likely that StcE lowers mucin levels by MUC2 degradation. However, other mechanisms related to mucin glycoprotein synthesis and secretion cannot be excluded at this stage. Diminished mucus reduction in ΔstcE-infected cells was accompanied by a decrease in A/E lesion formation despite adhesion levels comparable to the wild-type strain. Our findings confirm previous results in HEP-2 cells demonstrating reduced actin pedestal formation but not overall adherence by ΔstcE versus wild-type EHEC (Grys et al., 2005). HEP-2 cells do not secrete a mucus layer, and the authors suggested that StcE promotes intimate adherence by cleaving cell surface mucins and thereby exposing host cell receptors. To evaluate our findings in a physiologically relevant setting, we used IVOC of human colonic biopsies to investigate the impact of StcE on mucus production and EHEC adherence ex vivo. Previous studies from our laboratory have shown that EHEC binds to human colonic biopsy epithelium by forming A/E lesions (Lewis et al., 2015). Similar to our results in LS174T cells, reduction of the inner MUC2-containing mucus layer in IVOC was dependent on the presence of catalytically active StcE. However, lack of StcE caused a more pronounced effect on EHEC binding than in the cell line model with an almost complete loss of adherence to the colonic epithelium. It is likely that infection kinetics, environmental cues or host response may fine-tune expression and/or activity of StcE and other EHEC mucinases, and this may explain the differences in StcE-mediated mucus reduction observed in IVOC and colonic organoids (In et al., 2016).

Notably, some decrease in mucus levels independent of StcE was evident in LS174T cells and colonic biopsies, suggesting the activity of other mucinolytic enzymes during EHEC infection. Apart from StcE, another type II-secreted zinc metalloprotease has recently been identified in intestinal and extraintestinal E. coli strains (Nesta et al., 2014). Although Sse facilitates mucin penetration of extraintestinal E. coli in HT-29 MTX cells and enhances bacterial adhesion to the epithelial surface (Valeri et al., 2015), this protein is rarely detected in EHEC and therefore unlikely to contribute to its pathogenesis (Feng et al., 2007; Nesta et al., 2014).

In summary, our studies have shown that the EHEC-secreted metalloprotease StcE reduces mucus levels and promotes bacterial adherence to human colonic epithelium in vitro and ex vivo. Given the lack of effective prevention and treatment strategies, StcE may represent a suitable target for drug and vaccine development against EHEC infection in the human gut.

### 4 Experimental procedures

#### 4.1 Bacterial culture

EHEC strains used in this study are listed in Table 1. Bacteria were cultured on Luria-Bertani (LB) agar or as standing overnight cultures in LB broth.

forming units were counted the next day. Lysates were serially diluted in PBS, and appropriate dilutions were incubated or washed vigorously in PBS to remove non-adherent bacteria and processed according to further applications.

4.2 | Cell culture

HT-29 (ECACC 91072201), Caco-2 (ECACC 86010202), and LS174T human colon carcinoma cells (ECACC 87060401) were cultured in Dulbecco’s Modified Eagle's Medium (DMEM, Sigma) supplemented with 10% foetal calf serum, 4mM L-glutamine and 1× nonessential amino acids (Sigma). Cell lines were grown at 37 °C in a 5% CO2 atmosphere.

4.3 | Infection of cell lines

Cells were seeded at a density of 10^9 (LS174T, Caco-2) or 1.2 x 10^5 cells per well (HT-29) into 24-well plates and grown for 7 days to reach full confluence. For immunofluorescence staining, cells were grown on glass coverslips. For infection, supplemented DMEM was replaced with plain DMEM medium, and 20 μl bacterial overnight culture (approximately 10^7 bacteria) were added to each well. Infected cells were incubated at 37 °C in a 5% CO2 atmosphere for up to 6 hr. Medium was exchanged after 3 hr to prevent bacterial overgrowth and acidification. At the end of infection, cells were washed three times with phosphate-buffered saline (PBS) to remove non-adherent bacteria and processed according to further applications.

4.4 | Quantification of adherence

Infected cells were lysed with 1% Triton X-100 in PBS for 15 min. Cell lysates were serially diluted in PBS, and appropriate dilutions were plated on LB agar. Plates were incubated overnight, and colony-forming units were counted the next day.

4.5 | IVOC of endoscopic biopsies

This study was performed with approval from the University of East Anglia Faculty of Medicine and Health Ethics Committee (ref 2010/11-030). All samples were registered with the Norwich Biorepository (NRES ref 08/h0304/85 + 5). Biopsy samples from the transverse colon were obtained with informed consent during colonoscopy of adult patients. Samples were taken from macroscopically normal areas, transported to the laboratory in IVOC medium and processed within the next hour. IVOC was performed as described previously (Lewis et al., 2015). Briefly, biopsies were mounted on foam supports in 12-well plates and incubated with 25 μl bacterial overnight culture (approximately 10^7 bacteria). Samples were incubated for 8 hr on a rocking platform at 37 °C in a 5% CO2 atmosphere. At the end of the experiment, tissues were either immediately fixed for mucin staining or washed vigorously in PBS to remove the mucus layer and evaluate bacterial adhesion to the epithelium.

4.6 | Immunofluorescence staining

Cells and biopsy samples were fixed in 3.7% formaldehyde/PBS for 20 min at room temperature or in Carnoy’s fixative (60% dry ethanol, 30% chloroform, and 10% glacial acetic acid) overnight at 4 °C for mucin staining. Samples were permeabilised with 0.1% Triton X-100/PBS if required and were blocked with 0.5% bovine serum albumine (BSA)/PBS for 20 min. Coverslips and tissues were sequentially incubated with primary antibodies (anti-MUC2 and anti-MUC5AC from Santa Cruz, anti-E. coli from Abcam) for 1 hr, followed by incubation in Alexa Fluor 488- or Alexa Fluor 568-conjugated secondary antibodies (Life Technologies) for 30 min. Cell nuclei and filamentous actin were counterstained with DAPI (Roche) and Fluorescein isothiocyanate-conjugated phalloidin (Sigma) for 30 min, respectively. Cell monolayers and biopsy samples were mounted with Vectashield mounting medium (Vector Labs) and analysed using an Axio Imager M2 motorised fluorescence microscope (Zeiss). MUC2 fluorescence staining was measured by taking images from 10 random fields of view (20× magnification) and determining the integrated density with ImageJ software (https://imagej.nih.gov/ij/). EHEC actin pedestal formation on LS174T cells was quantified by taking images from 10 random fields of view (63× magnification) and counting total bacteria and bacteria associated with actin pedestals. EHEC colonisation of colonic biopsies was evaluated by counting adherent bacteria in a surface area of 1 mm².

4.7 | SDS-agarose gel electrophoresis and Western blotting

Confluent LS174T cell monolayers were lysed in ice-cold lysis buffer (1% Triton X-100, 20mM HEPES, 140mM NaCl, pH 7.4) containing protease inhibitor cocktail (Sigma). Triton-insoluble proteins were pelleted by centrifugation, and supernatants were denatured in reducing lithium dodecyl sulfate sample buffer (Thermo Fisher Scientific). Mucin glycoproteins were separated by SDS-agarose gel electrophoresis as described previously (Warren, Krzesinski, & Greaser, 2003). Briefly, a 1cm 12% polyacrylamide plug was cast using 10 x 8cm glass plates and 1.5mm spacers (Bio-Rad). After polymerisation, this was overlaid by a 1% agarose gel (Agarose LE, Promega) prepared in running buffer (50mM Tris, 384mM glycine, and 0.1% SDS) containing 30% glycerol. Samples were electrophoresed at 13 mA for 45 min at 4 °C in a Mini-PROTEAN Tetra Cell device (Bio-Rad). For electroblotting, gels were placed into NuPAGE transfer buffer (Thermo Fisher Scientific) containing 10% methanol and blotted to 0.45 μm Hybond PVDF membrane (GE Healthcare Life Sciences) at 40 V for 2 hr 20 min at 4 °C in an Xcell II blot module (Thermo Fisher Scientific). Membranes were subsequently blocked with 3% BSA in Tris-buffered saline/0.05% Tween-20 for 60 min and incubated with mouse anti-MUC2 (abcam) overnight at 4 °C. After washing, blots were incubated with horseradish peroxidase-conjugated goat anti-mouse IgG (Invitrogen) and developed using enhanced chemiluminescence (Immobilon Western, Millipore) and a FluorChem E Imager (ProteinSimple). Signal intensity was quantified using ImageJ software.

4.8 | Bacterial mutagenesis and complementation

An stcE mutant in strain TUV 93-0 was generated by Lambda Red recombination (Datsonko & Wanner, 2000). Briefly, the helper plasmid pKD46 carrying the Lambda Red recombinase was electroporated into
PCR amplifying to generate pACYC184 low copy
CGCACCGTCTC
CCCTCCGATGATAGTGG
Lambda Red recombinase expression was induced with 0.2% arabinose.

The resulting PCR product was electroporated into pKD46-recombinant TUV 93-0, and Lambda Red recombinase expression was induced with 0.2% arabinose. The product was electroporated into pKD46-recombinant TUV 93-0, and Lambda Red recombinase expression was induced with 0.2% arabinose.

amplicons were mixed in equimolar amounts, ligated, and PCR amplified from the pO157 plasmid of TUV 93 (5′-GAAGCTTGCTGAACGCATCGGTG-′-GCAAGAAGTCTGCTGCTTGTC-3′) using primers M1 and M2 and external primers E1 (5′-GCCCTGAAGCTTGCAGCATCGCG-3′) and E2 (5′-CCTCCGCTTCTCCTCAGATGATGGTGGTCC-3′) flanking the site of mutation.

For complementation, the stcE gene and its promoter were PCR amplified from the pO157 plasmid of TUV 93-0 using primers stcE-F (5′-CTTCTGAGGTTGCTTTAAACCCCG-3′) and stcE-R (5′-AAGTGGCCGCACCGTCTC-3′). The PCR product was blunt end-ligated into the low copy-number vector pACYC184 (NEB) digested with NruI (NEB) to generate pACYC184-stcE. Complementing plasmid with catalytically inactive StcE E447D (Yu, Worrall, & Strynadka, 2012) was created by PCR amplifying stcE from pACYC184-stcE using primers pairs stcE-F/ stcE_mut-R (5′-TCTGACTGAACTCATTCCC-3′) and stcE_mut-F (5′-TTTGAGGTCATAATTTATGGTCTTGG-3′)/stcE_R (5′-AAGTCTGCTGCTTGTC-3′). The resulting amplicons were mixed in equimolar amounts, ligated, and PCR amplified using primers stcE-F and stcE-R. Amplification products were subsequently blunt-end ligated into NruI-restricted pACYC184 to generate pACYC184-stcE_E447D. Plasmids were transformed into TUV 93-0 ΔstcE by electroporation, and recombinant clones were selected on LB plates containing 50 μg/mL kanamycin, and clones were cured from pKD46 by incubation at 43 °C. Mutagenesis of stcE was confirmed by sequencing (Eurofins) using primers stcE-ΔGTGGAATGCAGATACGCAGG/stcE-ΔF4/stcE-Δ′-F

4.10 | Statistics

All data are shown as means ± standard error of the mean of three independent experiments performed in duplicate unless indicated otherwise. Statistical analysis was performed using GraphPad Prism software (version 5). Student’s t test or one-way analysis of variance with Tukey’s multiple comparisons test was used to determine differences between two or multiple groups, respectively. For biopsy data, the nonparametric Kruskal-Wallis test with Dunn’s post-test was used to analyse multiple groups. A p value of <0.05 was considered significant.

ACKNOWLEDGEMENTS
