Abstract. This paper presents a comprehensive description and benchmark evaluation of the tropospheric gas-phase chemistry component of the Multiscale Online Nonhydrostatic Atmosphere Chemistry model (NMMB-MONARCH), formerly known as NMMB/BSC-CTM, that can be run on both regional and global domains. Here, we provide an extensive evaluation of a global annual cycle simulation using a variety of background surface stations (EMEP, WDCGG and CASTNET), ozonesondes (WOUDC, CMD and SHADOZ), aircraft data (MOZAIC and several campaigns), and satellite observations (SCIAMACHY and MOPITT). We also include an extensive discussion of our results in comparison to other state-of-the-art models. We note that in this study, we omitted aerosol processes and some natural emissions (lightning and volcano emissions).

The model shows a realistic oxidative capacity across the globe. The seasonal cycle for CO is fairly well represented at different locations (correlations around 0.3–0.7 in surface concentrations), although concentrations are underestimated

in spring and winter in the Northern Hemisphere, and are overestimated throughout the year at 800 and 500 hPa in the Southern Hemisphere.

Nitrogen species are well represented in almost all locations, particularly NO₂ in Europe (root mean square error – RMSE – below 5 ppb). The modeled vertical distributions of NO_x and HNO₃ are in excellent agreement with the observed values and the spatial and seasonal trends of tropospheric NO₂ columns correspond well to observations from SCIAMACHY, capturing the highly polluted areas and the biomass burning cycle throughout the year. Over Asia, the model underestimates NO_x from March to August, probably due to an underestimation of NO_x emissions in the region. Overall, the comparison of the modeled CO and NO₂ with MOPITT and SCIAMACHY observations emphasizes the need for more accurate emission rates from anthropogenic and biomass burning sources (i.e., specification of temporal variability).

The resulting ozone (O_3) burden (348 Tg) lies within the range of other state-of-the-art global atmospheric chemistry models. The model generally captures the spatial and seasonal trends of background surface O_3 and its vertical distribution. However, the model tends to overestimate O_3 throughout the troposphere in several stations. This may be attributed to an overestimation of CO concentration over the Southern Hemisphere leading to an excessive production of O_3 or to the lack of specific chemistry (e.g., halogen chemistry, aerosol chemistry). Overall, O_3 correlations range between 0.6 and 0.8 for daily mean values. The overall performance of the NMMB-MONARCH is comparable to that of other state-of-the-art global chemistry models.

1 Introduction

Tropospheric ozone (O_3) is a radiatively active gas interacting with solar and terrestrial radiation that is mainly produced during the photochemical oxidation of methane (CH_4), carbon monoxide (CO) and non-methane volatile organic compounds (NMVOCs) in the presence of nitrogen oxides (NO_x) (Crutzen, 1974; Derwent et al., 1996). Downward transport from the stratosphere, where O_3 is created by photolysis of oxygen (O_2) molecules, is also an important source of tropospheric O_3 (Stohl et al., 2003; Hsu and Prather, 2009). In urban areas, O_3 is a major component of “smog”, which can cause a number of respiratory health effects (WHO, 2014). Since the pre-industrial era, changes in emissions of O_3 precursors from anthropogenic and biomass burning sources have modified the distribution of tropospheric O_3 and other trace gases (Lamarque et al., 2013). Tropospheric O_3 , with an average lifetime on the order of weeks, is highly variable in space and time, and air quality models (AQMs) are required to predict harmful levels of O_3 along with its precursors and other trace gases.

AQMs are driven by meteorological fields and emissions of chemical species. They include a chemical mechanism for representing gas-phase and aerosol atmospheric chemistry, a photolysis scheme describing the photo-dissociation reactions driven by sunlight, dry and wet deposition schemes to account for the removal of pollutants from the atmosphere, and the characterization of the downward transport of stratospheric O_3 . The development of AQMs and meteorological models (MMs) evolved as separate fields (offline approach) due to complexity and limitations in computer resources. The offline approach requires lower computational capacity, but also involves a loss of essential information on atmospheric processes whose timescale is smaller than the output time rate of the meteorological model (Baklanov et al., 2014). Nowadays, owing to a general increase in computer capacity, online coupled meteorology–chemistry models are being increasingly developed and used by the scientific community, which recognizes the advantages of the online ap-

proach (Byun, 1990). Overviews of online AQM–MM models are available in the literature (Zhang, 2008; Baklanov et al., 2014).

Several global AQMs have been developed during the last decades, including the multiscale GEM-AQ (online, $1.5^\circ \times 1.5^\circ$) (Gong et al., 2012), TM5-chem-v3.0 (offline, $3^\circ \times 2^\circ$) (Huijnen et al., 2010), LMDZ-INCA (offline, $3.8^\circ \times 2.5^\circ$) (Folberth et al., 2006), the GATOR-GCMM (online, $4^\circ \times 5^\circ$) (Jacobson, 2001), the IFS-MOZART used in the MACC project (online, $80 \text{ km} \times 80 \text{ km}$) (Flemming et al., 2009), C-IFS recently developed at ECMWF (online, $80 \text{ km} \times 80 \text{ km}$) (Flemming et al., 2015), and MOZART-4 (offline, $2.8^\circ \times 2.8^\circ$) (Emmons et al., 2010). Most of these models have been applied at coarse resolutions with simplified chemical schemes. Currently, the systems are being updated and prepared for higher-resolution applications.

In this contribution, we describe the gas-phase chemistry of the Multiscale Online Nonhydrostatic Atmosphere Chemistry model (NMMB-MONARCH), a chemical weather prediction system formerly known as NMMB/BSC-CTM that can be run either globally or regionally (Pérez et al., 2011; Jorba et al., 2012). The NMMB-MONARCH, developed at the Barcelona Supercomputing Center, is based on the coupling of the meteorological Nonhydrostatic Multiscale Model on the B-grid (NMMB; Janjic and Gall, 2012) with a chemistry module. We provide a thorough evaluation of the gas-phase chemistry over a 1-year period for the global domain using a horizontal resolution of $1.4^\circ \times 1^\circ$.

The NMMB-MONARCH configured as a limited area (regional) model has recently participated in the Air Quality Model Evaluation International Initiative Phase2 (AQMEII-Phase2) intercomparison exercise (Im et al., 2014). Badia and Jorba (2014) also provided a detailed evaluation of the gas-phase chemistry for the year 2010 over Europe in the context of AQMEII-Phase2. The initial model developments focused on the implementation of the mineral dust aerosol component (NMMB/BSC-Dust; Pérez et al., 2011; Haustein et al., 2012) and the sea-salt aerosol component (Spada et al., 2013, 2015). The implementation and evaluation of other relevant aerosols will soon be described elsewhere (Spada et al., 2017). This initiative aims at developing a fully coupled chemical multiscale (global/regional) weather prediction system that resolves gas–aerosol–meteorology interactions and provides initial and boundary conditions for embedded high-resolution nests in a unified dynamics–physics–chemistry environment.

The paper is organized as follows. In Sect. 2, we provide a description of the atmospheric driver, the gas-phase chemistry module, and the model configuration including the online biogenic emissions. Section 3 presents an overview of the model setup with a description of the chemical and meteorological initial conditions, and the anthropogenic and biomass burning emissions implemented for this experiment. We illustrate the capability of the NMMB-MONARCH to reproduce the atmospheric composition by evaluating the

model with ground-based monitoring stations, ozonesondes, aircraft data, climatological vertical profiles and satellite retrievals, which are described in Sect. 4. The results of the model performance are discussed in Sect. 5 for the year 2004. The last section summarizes the conclusions of this work.

2 Model description

The NMMB-MONARCH is a fully online multiscale chemical weather prediction system for regional and global-scale applications (Pérez et al., 2011; Jorba et al., 2012). The system is based on the meteorological Nonhydrostatic Multiscale Model on the B-grid (NMMB; Janjic and Gall, 2012), developed and widely verified at the National Centers for Environmental Prediction (NCEP). The model couples online the NMMB with the gas-phase and aerosol continuity equations to solve the atmospheric chemistry processes in detail. The model is designed to account for the feedbacks among gases, aerosol particles and meteorology. Currently, it can consider the direct radiative effect of aerosols while ignoring cloud–aerosol interactions. In this work, only the gas-phase chemistry is used; thus, no interaction between gas phase and aerosol phase is applied. In this section we provide a concise description of the NMMB and the gas-phase chemistry module of the NMMB-MONARCH.

2.1 The Nonhydrostatic Multiscale Model on the B-grid

The Nonhydrostatic Multiscale Model on the B-grid (NMMB; Janjic, 2005; Janjic and Gall, 2012) was conceived for short- and medium-range forecasting over a wide range of spatial and temporal scales, from large eddy simulations (LES) to global simulations. Its unified nonhydrostatic dynamical core allows for running of either regional or global simulations, both including embedded regional nests. The NMMB has been developed within the Earth System Modeling Framework (ESMF) at NCEP, following the general modeling philosophy of the NCEP regional Weather Research and Forecasting (WRF) Nonhydrostatic Mesoscale Model (NMM; Janjic et al., 2001; Janjic, 2003). The regional NMMB has been the operational regional North American Mesoscale (NAM) model at NCEP since October 2011. The numerical schemes used in the model were designed following the principles presented in Janjic (1977, 1979, 1984, 2003). Isotropic horizontal finite volume differencing is employed so that a variety of basic and derived dynamical and quadratic quantities are conserved. Among these, the conservation of energy and enstrophy (Arakawa, 1966) improves the accuracy of the non-linear dynamics. The hybrid pressure-sigma coordinate is used in the vertical direction and the Arakawa B-grid is applied in the horizontal direction. The global model on the latitude–longitude grid with polar filtering was developed as the reference version, and

other geometries such as the cubed sphere are currently being tested. The regional model is formulated on a rotated longitude–latitude grid, with the Equator of the rotated system running through the middle of the integration domain, resulting in more uniform grid distances. The nonhydrostatic component of the model dynamics is introduced through an add-on module that can be turned on or off, depending on the resolution. The operational physical package includes (1) the Mellor–Yamada–Janjic (MYJ) level 2.5 turbulence closure for the treatment of turbulence in the planetary boundary layer (PBL) and in the free atmosphere (Janjic et al., 2001), (2) the surface layer scheme based on the Monin–Obukhov similarity theory (Monin and Obukhov, 1954) with an introduced viscous sublayer over land and water (Zilitinkevich, 1965; Janjic, 1994), (3) the NCEP NOAA (Ek et al., 2003) or the LISS land surface model (Vukovic et al., 2010) for the computation of the heat and moisture surface fluxes, (4) the GFDL or RRTMG longwave and shortwave radiation package (Fels and Schwarzkopf, 1975; Mlawer et al., 1997), (5) the Ferrier grid-scale clouds and microphysics (Ferrier et al., 2002), and (6) the Betts–Miller–Janjic convective parametrization (Betts, 1986; Betts and Miller, 1986; Janjic, 1994, 2000). Vertical diffusion is handled by the surface layer scheme and by the PBL scheme. Lateral diffusion is formulated following the Smagorinsky non-linear approach (Janjic, 1990). Table 1 describes the main configuration of the meteorological model used in this work.

2.2 Gas-phase chemistry module

The tropospheric gas-phase chemistry module is coupled online within the NMMB. Different chemical processes were implemented following a modular operator splitting approach to solve the advection, diffusion, chemistry, dry and wet deposition, and emission processes. Meteorological information is available at each time step to solve the chemical processes. In order to maintain consistency with the meteorological solver, the chemical species are advected and mixed at the corresponding time step of the meteorological tracers using the same numerical schemes implemented in the NMMB. The advection scheme is Eulerian, positive definite and monotone, maintaining a consistent mass conservation of the chemical species within the domain of study (Janjic et al., 2009; Tang et al., 2009; Janjic and Gall, 2012).

2.2.1 Chemical-phase reaction mechanism

Several chemical mechanisms can be implemented within the NMMB-MONARCH. A modular coupling with the Kinetic PreProcessor (KPP) package (Damian et al., 2002; Sandu and Sander, 2006) allows the model to maintain wide flexibility. Additionally, an Eulerian backward iterative solver (Hertel et al., 1993) was implemented as a complementary option to the KPP solvers to allow the model to run with a fast ordinary differential equation solver at global scales. For the

present study, we use a Carbon-Bond family mechanism, the Carbon Bond 2005 (CB05; Yarwood et al., 2005), an updated version of the Carbon Bond IV (CB4) lumped-structure-type mechanism (Gery et al., 1989). CB4 was formulated focusing on limited domain extent, urban and regional environments and for planetary boundary layer chemistry. CB05 extends its applicability from urban to remote tropospheric conditions and is suitable for global applications. CB05 was evaluated against smog chamber data from the University of California, Riverside, and the University of North Carolina (Yarwood et al., 2005). It includes 51 chemical species and solves 156 reactions (see Tables S1 and S2 in the Supplement). Both the organic chemistry of methane and ethane, and the chemistry of methylperoxy radical, methyl hydroperoxide and formic acid are treated explicitly. The higher organic peroxides, organic acids, and peracids are treated as lumped species. Following its main design, CB05 defines proxy single and double carbon bond species, paraffin and an olefin bond, respectively, and it introduces the internal olefin species. The rate constants were updated based on evaluations from Atkinson et al. (2004) and Sander et al. (2006). Organic compounds not explicitly treated are apportioned to the carbon-bond species based on the molecular structure and following Yarwood et al. (2005) assignments from VOC species to CB05 model species. The concentration of methane is considered constant (1.85 ppm) in this study.

2.2.2 Photolysis scheme

One of the most important processes determining tropospheric composition is the photo-dissociation of trace gases. Table S3 lists the photolysis reactions considered. To compute the photolysis rates, we implemented the Fast-J (Wild et al., 2000) online photolysis scheme. Fast-J has been coupled with the physics of each model layer (e.g., clouds and absorbers such as O₃). The optical depths of grid-scale clouds from the atmospheric driver are considered by using the fractional cloudiness based on relative humidity (Fast et al., 2006). The main advantages of Fast-J are the optimization of the phase function expansion into Legendre polynomials and the optimization of the integration over wavelength (Wild et al., 2000). The Fast-J scheme has been upgraded with CB05 photolytic reactions. The quantum yields and cross section for the CB05 photolysis reactions have been revised and updated following the recommendations of Atkinson et al. (2004) and Sander et al. (2006). The Fast-J scheme uses seven different wavelength bins appropriate for the troposphere to calculate the actinic flux covering from 289 to 850 nm (see Table VIII from Wild et al., 2000). In this work, aerosols are not considered in the photolysis rate calculation. This might produce an atmosphere excessively oxidized in regions where aerosols are significant (e.g., Bian et al., 2003; Real and Sartelet, 2011).

2.2.3 Dry-deposition scheme

The dry-deposition scheme is responsible for computing the flux of trace gases from the atmosphere to the surface. It is calculated by multiplying the concentration in the lowest model layer by the spatially and temporally varying deposition velocity:

$$\frac{\partial C_i}{\partial t}_{\text{dry-dep}} = -C_i v_d, \quad (1)$$

where t is the time, i is the gas-phase species, C_i is the concentration of the gas in the lowest model layer, and v_d is the dry-deposition velocity. At each time step, v_d is calculated according to

$$|v_d| = \frac{1}{(R_a + R_b + R_c)}, \quad (2)$$

where R_a is the aerodynamic resistance (depends only on atmospheric conditions), R_b is the quasilaminar sublayer resistance (depends on friction velocity and molecular characteristics of gases), and R_c is the canopy or surface resistance (depends on surface properties and the reactivity of the gas). R_a and R_b are computed following their common definition (Seinfeld and Pandis, 1998), while R_c is simulated following Wesely (1989), where the surface resistance is derived from the resistances of the surfaces of the soil and the plants. The properties of the plants are determined using land-use data (from the USGS land use of the meteorological driver) and depend on the season. The surface resistance also depends on the diffusion coefficient, the reactivity, and the water solubility of the reactive trace gases.

2.2.4 Wet-deposition scheme

We use the scheme of Byun and Ching (1999) and Foley et al. (2010) to resolve the cloud processes affecting the concentration of 36 gases from the CB05 chemical mechanism. The processes included are grid-scale scavenging and wet deposition, subgrid-scale vertical mixing, scavenging and wet deposition for precipitating and non-precipitating clouds. Aqueous chemistry is neglected in version 1.0 of the model. At the moment, we consider only in-cloud scavenging, which is computed using the Henry's law equilibrium equation. The rate of change for in-cloud pollutant concentration is given by

$$\frac{\partial C_{i,\text{cld}}}{\partial t} = C_{i,\text{cld}} \frac{e^{-\alpha_i \tau_{\text{cld}}} - 1}{\tau_{\text{cld}}}, \quad (3)$$

where $C_{i,\text{cld}}$ is the gas concentration within the cloud (ppm), τ_{cld} is the cloud timescale (s), and α_i is the scavenging coefficient for the gas species that is calculated as

$$\alpha_i = \frac{1}{\tau_{\text{washout}} \left(1 + \frac{\text{TWF}}{H_i} \right)}, \quad (4)$$

where H_i is the Henry's law coefficient for the gas species (M atm^{-1}), $\text{TWF} = \rho_{\text{H}_2\text{O}} / (W_T R T)$ is the total water fraction (where $\rho_{\text{H}_2\text{O}}$ is the density of water (kg m^{-3}), W_T is the total mean water content (kg m^{-3}), R is the universal gas constant, and T is the in-cloud air temperature (K)), and τ_{washout} is the washout time (s), i.e., the amount of time required to remove all of the water from the cloud volume at a specified precipitation rate, which is given by

$$\tau_{\text{washout}} = \frac{W_T \Delta Z_{\text{cld}}}{\rho_{\text{H}_2\text{O}} P_r}, \quad (5)$$

where ΔZ_{cld} is the cloud thickness (m) and P_r is the precipitation rate (m s^{-1}). Both grid-scale and subgrid-scale scavenging are computed with Eq. (3), where τ_{cld} is 1 h for subgrid-scale clouds, and the chemistry time step for grid-scale clouds. Wet deposition is computed following the algorithm of Chang et al. (1987), which depends upon P_r and the gas concentration within the cloud $C_{i,\text{cld}}$. Thus, the wet deposition is given by

$$\text{wdep}_i = \int_0^{\tau_{\text{cld}}} C_{i,\text{cld}} P_r dt. \quad (6)$$

The sub-grid cloud scheme implemented solves convective mixing, scavenging and wet deposition of a representative cloud within the grid cell following the CMAQ and RADMV2.6 model schemes (Byun and Ching, 1999; Chang et al., 1987). Precipitating and non-precipitating sub-grid clouds are considered. The latter are categorized as pure fair weather clouds and non-precipitating clouds and may coexist with precipitating clouds (Byun and Ching, 1999; Foley et al., 2010).

2.2.5 Upper boundary conditions

Because the model focuses on the troposphere, stratospheric chemistry is taken into account using a simplified approach. Above 100 hPa, mixing ratios of several species (NO , NO_2 , N_2O_5 , HNO_3 and CO) are initialized each day from a global chemical model, MOZART-4 (Emmons et al., 2010). For O_3 , an important reactive gas requiring a more refined representation in the stratosphere, we use a linear O_3 stratospheric scheme, COPCAT (Monge-Sanz et al., 2011). COPCAT is based on the approach of Cariolle and Déqué (1986), which represented the first effort to include a linearized O_3 scheme (named Cariolle v1.0) in a three-dimensional model.

In COPCAT the linear coefficients are obtained at equilibrium from the TOMCAT/SLIMCAT box model (Chipperfield, 2006). These terms are presented as functions of 24 latitudes, 24 model vertical levels and 12 months.

Heterogeneous processes describing the polar stratospheric chemistry are non-linear and depend on the three-dimensional structure of the atmosphere. COPCAT includes complete heterogeneous processes in their coefficients, con-

Table 2. Emission totals by category in Tg(species) year⁻¹ for 2004. Anthropogenic and biomass burning emissions applied in this study are based on Lamarque et al. (2013). Ocean and soil natural emissions are based on the POET global inventory (Granier et al., 2005). Biogenic emissions are computed online from MEGAN (Guenther et al., 2006).

Species	Anthrop.	Bio. burning	Biogenic	Soil	Ocean
CO	610.5	459.6	148.13	–	19.85
NO	85.8	5.4	16.54	11.7	–

Ethylene (C ₂ H ₄)	3.32	2.71	32.03	–	–

sidering heterogeneous and gas-phase chemistry to be consistent when applied in this linear O₃ parameterization. This kind of parameterization is in better agreement with the current state of knowledge of stratospheric heterogeneous chemistry than previous schemes (Monge-Sanz et al., 2011). For further description of the approach and information on the biases of the stratosphere ozone simulated by the COPCAT scheme, the reader is referred to Monge-Sanz et al. (2011).

2.2.6 Online natural emissions

Natural emissions of gaseous pollutants include biogenic emissions, soil emissions, emissions from lightning, and emissions from oceans and volcanoes. Currently, soil and oceanic emissions in the model are prescribed as described in Sect. 3.1 and emissions from lightning and volcanoes are not considered. The omission of lightning emissions may have a significant impact on the oxidation of the middle and upper troposphere. Only biogenic emissions, which strongly depend on meteorological fields and vegetation cover, are calculated online. They are computed using the Model of Emissions of Gases and Aerosols from Nature version 2.04 (MEGANv2; Guenther et al., 2006). MEGAN is able to estimate the net emission rate of gases and aerosols from terrestrial ecosystems into the above-canopy atmosphere. MEGAN canopy-scale emission factors differ from most other biogenic emission models, which use leaf-scale emission factors and cover more than 130 non-methane volatile organic compounds (NMVOCs). All the MEGAN NMVOCs are speciated following the CB05 chemical mechanism; thus, emissions for isoprene, lumped terpenes, methanol, nitrogen monoxide, acetaldehyde, ethanol, formaldehyde, higher aldehydes, toluene, carbon monoxide, ethane, ethene, paraffin carbon bond, and olefin carbon bond are considered within the model. Biogenic emissions are computed every

hour to account for evolving meteorological changes in solar radiation and surface temperature. Thus, the weather-driving variables considered are temperature at 2 m and incoming shortwave radiation at the surface.

Figure S1 in the Supplement shows the modeled emission for isoprene and terpenes for January and July 2004, and Table 2 lists the global annual emissions for isoprene, monoterpenes and other important NMVOCs. Biogenic isoprene emissions used in this study amount to 683.16 Tg year⁻¹. While other global models have lower estimates (Huijnen et al., 2010; Horowitz et al., 2003; Emmons et al., 2010), MEGAN isoprene emissions typically range from about 500 to 750 Tg year⁻¹ (Guenther et al., 2006). These estimates largely depend on the assumed land cover, emission factors, and meteorological parameters. Therefore, the emission uncertainties and their impacts upon surface O₃ are associated with uncertainties in these inputs. Ashworth et al. (2010) obtained emission reductions of 3 and 7 % when using daily and monthly meteorological data, respectively, instead of hourly data, with reductions reaching up to 55 % in some locations. Marais et al. (2014) performed several sensitivity model runs to study the impact of different model input and settings on isoprene estimates that resulted in differences of up to ±17 % compared to a baseline. In our study, weather inputs are based on previous day 24 h averages and data of the hour of interest.

3 Model setup

The model is set up as global with a horizontal grid spacing of 1.4° × 1° and 64 vertical layers up to 1 hPa. The depth of the bottom layer is below 40 m. The dynamics fundamental time step is set to 180 s and the chemistry processes are solved every 720 s. The radiation, photolysis scheme

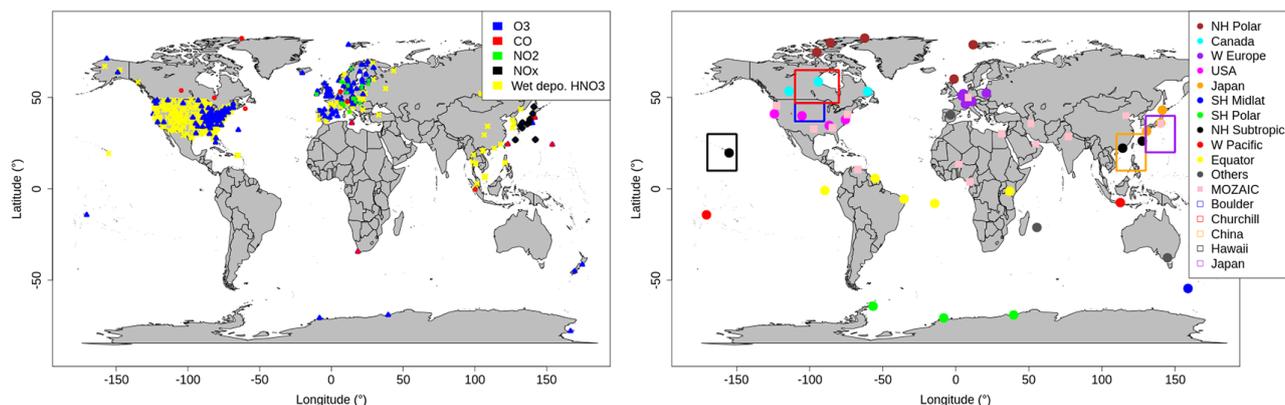

Figure 1. Stations used for the evaluation of the NMMB-MONARCH model. On the left, surface-monitoring rural stations of O₃ (blue triangle), CO (red circle), NO₂ (green square cross) and NO_x (black diamond) are shown. Moreover, wet deposition of HNO₃ measurement locations (yellow cross) is presented. On the right, locations of the ozonesondes used are shown. Ozonesondes are grouped by the following regions: NH Polar (brown circle), Canada (cyan circle), W Europe (purple circle), US (pink circle), Japan (orange circle), SH Midlat (blue circle), SH Polar (green circle), NH Subtropics (black circle), W Pacific (red circle), Equator (yellow circle) and Others (gray circle). In addition, CO vertical profiles from the MOZAIC aircraft campaign (pink square) are presented. Finally, large rectangles show areas for the climatology analysis (NO_x, PAN and HNO₃) for Boulder (blue), Churchill (red), China (orange), Hawaii (black) and Japan (purple).

and biogenic emissions are computed every hour. We use NCEP/Final Analysis (FNL) as initial conditions for the meteorological driver, and we reinitialize the meteorology every 24 h to reproduce the observed transport. We performed a spin-up of 1 year using initial chemistry conditions from the MOZART-4 global atmospheric model (Emmons et al., 2010) prior to the 2004 annual cycle simulation that is evaluated in the present study. Table 1 describes the main configuration of the model. The feedback between chemistry and meteorology is not considered in this study.

3.1 Emissions

The global emissions used in this study are based on the Atmospheric Chemistry and Climate Model Intercomparison Project (ACCMIP; Lamarque et al., 2013), which includes emissions from anthropogenic and biomass burning sources at $0.5^\circ \times 0.5^\circ$ horizontal resolution (Lamarque et al., 2010). Note that this methodology involves assuming 2004 emissions equivalent to the best estimate reported for the ACCMIP for the year 2000. Therefore specific events that occurred during 2004 (e.g., large summer wildfires in Alaska and Canada) are not described. The ACCMIP inventory is a combination of several existing regional and global inventories. The surface anthropogenic emissions are based on two historical emission inventories, namely RETRO (1960–2000; Schultz and Rast, 2007) and EDGAR-HYDE (1890–1990; Van Aardenne et al., 2005), and monthly variations for biomass burning and ship and aircraft emissions are provided. One limitation is that land-based anthropogenic emissions have constant values for the entire year. Lamarque et al. (2010) present a comparison of the annual total CO anthropogenic and biomass burning

emissions ($\text{Tg}(\text{CO}) \text{ year}^{-1}$) for different regional and global emission inventories for the year 2000 (see Table 5 of this paper). Note that ACCMIP global CO anthropogenic emissions are significantly higher ($610.5 \text{ Tg CO year}^{-1}$) than other emissions inventories (e.g., RETRO with $476 \text{ Tg CO year}^{-1}$, EDGAR-HYDE with $548 \text{ Tg CO year}^{-1}$, and GAINS with $542 \text{ Tg CO year}^{-1}$).

Ocean and soil natural emissions are based on the POET (Granier et al., 2005) global inventory. Lightning and volcano emissions are not considered in this simulation. Biogenic emissions are computed using the MEGANv2.04 model as described in Sect. 2.2.6. NO emissions for January and July 2004 are shown in Fig. S1 and yearly totals for anthropogenic, biomass burning, biogenic, soil, and ocean emissions are summarized in Table 2.

To account for the sub-grid-scale vertical diffusion within the PBL, all the land-based anthropogenic emissions are emitted in the first 500 m of the model, biomass burning emissions from forests in the first 1300 m, biomass burning emissions from grass in the first 200 m, ocean emissions in the first 30 m and shipping emissions in the first 500 m. This vertical distribution of emissions has been derived after some sensitivity runs and it may not be appropriate for higher-resolution runs. The model does not include the attenuation of radiation due to aerosols in the photolysis scheme. Therefore, regions with strong biomass burning emissions may significantly overestimate chemical photolysis production (e.g., Bian et al., 2003; Real and Sartelet, 2011).

4 Observational data

4.1 Surface concentration and wet deposition

For the evaluation of ground-level gas concentrations, we selected background stations having hourly data (Fig. 1, left panel) from the World Data Center for Greenhouse Gases (WDCGG; <http://ds.data.jma.go.jp/gmd/wdcgg/>), the European Monitoring and Evaluation Programme (EMEP; <http://www.emep.int/>), the Clean Air Status and Trends Network in the United States (US) (CASTNET; <http://java.epa.gov/castnet/>) and the Acid Deposition Monitoring Network in

East Asia (EANET; <http://www.eanet.asia/>). For O₃, we used data from 41 WDCGG, 52 EMEP, 64 CASTNET and 11 EANET stations, covering Europe, the US, and a few locations in eastern Asia. We also selected 21 EMEP stations for NO₂, 10 EANET stations for NO_x and 14 WDCGG stations for CO.

The simulated wet deposition of HNO₃ is also compared against observed nitrate (HNO₃ and aerosol nitrate) wet deposition, including 260 measurements from the National Atmospheric Deposition Program (NADP; <http://nadp.sws.>

uiuc.edu/) network in North America, 51 from the EMEP network in Europe and 28 from EANET in eastern Asia.

4.2 Vertical structure: ozonesondes, MOZAIC and measurement campaigns

The surface evaluation is complemented with an assessment of the vertical structure of O₃ using ozonesondes from the World Ozone and Ultraviolet Radiation Data Center ozonesonde network (WOUDC; <http://woudc.org/data/explore.php>), the Global Monitoring Division (GMD; <https://www.esrl.noaa.gov/gmd/dv/ftpdata.html>) and the Southern Hemisphere Additional OZonesondes (SHADOZ; <http://croc.gsfc.nasa.gov/shadoz/>; Thompson et al., 2003a, b). Most stations provide between 4 and 12 profiles per month each year with a precision of $\pm 3\text{--}8\%$ in the troposphere (Tilmes et al., 2012). We followed the methodology of Tilmes et al. (2012) for the selection and treatment of the measurements. Table 3 lists the locations and the number of available measurements per season of the 39 ozonesonde stations used (also displayed in Fig. 1), as well as the regions where stations with similar O₃ profiles were aggregated.

Additional observations considered in this study are CO vertical profiles from the Measurement of Ozone, Water Vapor, Carbon Monoxide, Nitrogen Oxide by Airbus In-Service Aircraft (MOZAIC; <http://http://www.iagos.fr>). Based on the availability of data, we selected 14 airports (displayed in Fig. 1, right panel) covering different regions of the world during 2004. The number of vertical profiles available per season are provided in Table 4.

Nitric oxide (NO_x), peroxyacetyl nitrate (PAN) and acid nitric (HNO₃) vertical profiles are used from four different measurement campaigns: TOPSE (Atlas et al., 2003; Emmons et al., 2003), TRACE-P (Jacob et al., 2003), PEM-Tropics-B (Raper et al., 2001) and POLINAT-2 (Schumann

et al., 2000). Tropospheric data from these four previous campaigns were gridded onto global maps with resolution $5^\circ \times 5^\circ \times 1$ km, forming data composites of important chemical species in order to provide a picture of the global distributions (Emmons et al., 2000).

In this study, all the observations considered are within the simulated year (2004), with the exception of the vertical profiles obtained from measurement campaigns. Details on the geographical regions and periods for these campaigns are given in Table 5, and the locations are displayed in Fig. 1 (right panel).

4.3 Satellite data

Modeled tropospheric NO₂ columns are compared with SCanning Imaging Absorption spectroMeter for Atmospheric CHartography (SCIAMACHY, <http://www.sciamachy.org/>) satellite data. SCIAMACHY (on board of ENVISAT, which was operational from March 2002 to April 2012) is a passive remote sensing spectrometer measuring backscattered, reflected, transmitted or emitted radiation from the atmosphere and Earth's surface with a wavelength range between 240 and 2380 nm. The SCIAMACHY instrument has a spatial resolution of typically 60 km \times 30 km, and has three different viewing geometries: nadir, limb, and sun/moon occultation. Alternating nadir and limb views, global coverage is achieved in 6 days.

NO₂ daily data were obtained from the Institute of Environmental Physics, University of Bremen (http://www.iup.uni-bremen.de/does/scia_no2_data_tropos.htm), based on the Version 3.0 data product (Hilboll et al., 2013). This dataset is an improved extension of the data presented in Richter et al. (2005). Validation of the data product was performed in several studies (e.g., Petritoli et al., 2004; Heue et al., 2005). We used daily satellite overpasses of cloud-free

Table 5. Description of additional aircraft campaign data, including location and date.

(< 20 % cloud fraction) tropospheric vertical column densities (VCD_{trop} NO₂) from SCIAMACHY measurements using the limb–nadir matching approach, whose total uncertainty is estimated to vary between 35 and 60 % in heavily polluted cases and > 100 % in clean scenarios (Boersma et al., 2004).

Additionally, CO mixing ratios at 800 and 500 hPa were evaluated with the Measurement of Pollution in the Troposphere (MOPITT, <http://www2.acd.ucar.edu/mopitt>) instrument retrievals. MOPITT, on board of the NASA EOS-Terra satellite, is a gas filter radiometer and measures thermal infrared (near 4.7 μm) and near-infrared (near 2.3 μm) radiation, only during clear-sky conditions, with a ground footprint of about 22 km × 22 km. We used the MOPITT Version 5 (V5) Level 2 data product, which provides daily CO mixing ratios. MOPITT CO mixing ratios have been validated with in situ CO profiles measured from numerous NOAA/ESRL aircraft profiles in Deeter et al. (2013), and they were found to be positively biased by about 1 % and highly correlated ($r = 0.98$) at surface levels.

5 Model evaluation

This section presents the model evaluation with observations of relevant trace gases, and compares the results with other modeling studies available in the literature.

For the evaluation of daily surface-level O₃, we considered averages of temporally collocated 3-hourly values from the model and the observations. Section S1 of the Supplement presents the statistical measures calculated from the daily data. Ground-monitoring stations were selected with a maximum altitude of 1000 m. Temporal collocation was also considered when comparing to ozonesondes, MOZAIC, MOPITT and SCIAMACHY. For CO, averaging kernels were considered to represent the observational sensitivity at different pressure levels. When computing the modeled tropospheric columns of NO₂ the tropopause was assumed to be fixed at 100 hPa in the tropics and 250 hPa in the extratropics.

Similarly, the evaluation with aircraft campaigns was performed after remapping the model output to the resolution of the observed data composites (5° × 5° × 1 km). For some species, the model evaluation is given per sea-

sons: December–January–February (DJF), March–April–May (MAM), June–July–August (JJA) and September–October–November (SON).

5.1 Hydroxyl radical (OH)

One of the means for characterizing the general properties of an AQM is through its ability to simulate OH oxidation. OH is the main oxidant in the troposphere and is responsible for the removal of many compounds, thereby controlling their atmospheric abundance and lifetime. OH is mostly found in the tropical lower and mid troposphere and strongly depends on the levels of ultraviolet radiation and water vapor. Tropospheric OH formation is mainly due to O₃ photolysis, dominated by the tropics. Also, OH is directly connected to the chemistry of O₃ production since the initial reactions of O₃ formation (VOC + OH and CO + OH) are driven by OH. Hence, O₃ production rates depend on the sources and sinks of odd hydrogen radicals. Primary OH formation also includes the photolysis of HCHO and secondary VOC.

The tropospheric mean (air mass weighted) OH derived by the model is 11.5×10^5 molec cm⁻³, assuming a tropospheric domain ranging from 200 hPa to the surface. Note that previous studies suggest that the estimation of the mean OH does not depend on the definition of the tropopause (Voulgarakis et al., 2013). This value is in good agreement with other studies, e.g., Voulgarakis et al. (2013), where the mean OH concentration from 14 models for 2000 was estimated to be $11.1 \pm 1.8 \times 10^5$ molec cm⁻³, Spivakovsky et al. (2000) with 11.6×10^5 molec cm⁻³, and Prinn et al. (2001) with $9.4 \pm 0.13 \times 10^5$ molec cm⁻³.

The zonal mean OH concentrations for January, April, July and October 2004 are shown in Fig. 2. Seasonal differences reflect the impact of water vapor concentration and stratospheric O₃ column upon incident ultraviolet (UV) radiation (Spivakovsky et al., 2000; Lelieveld et al., 2002). The highest OH concentrations arise in the tropics throughout the year. In northern mid-latitudes, the highest OH concentrations are found during summer in the lower to middle troposphere. The latitudinal and seasonal variations are similar to the climatological mean in Spivakovsky et al. (2000), particularly the lower values in the extratropics. Peak concentrations are slightly larger compared to this climatology and other stud-

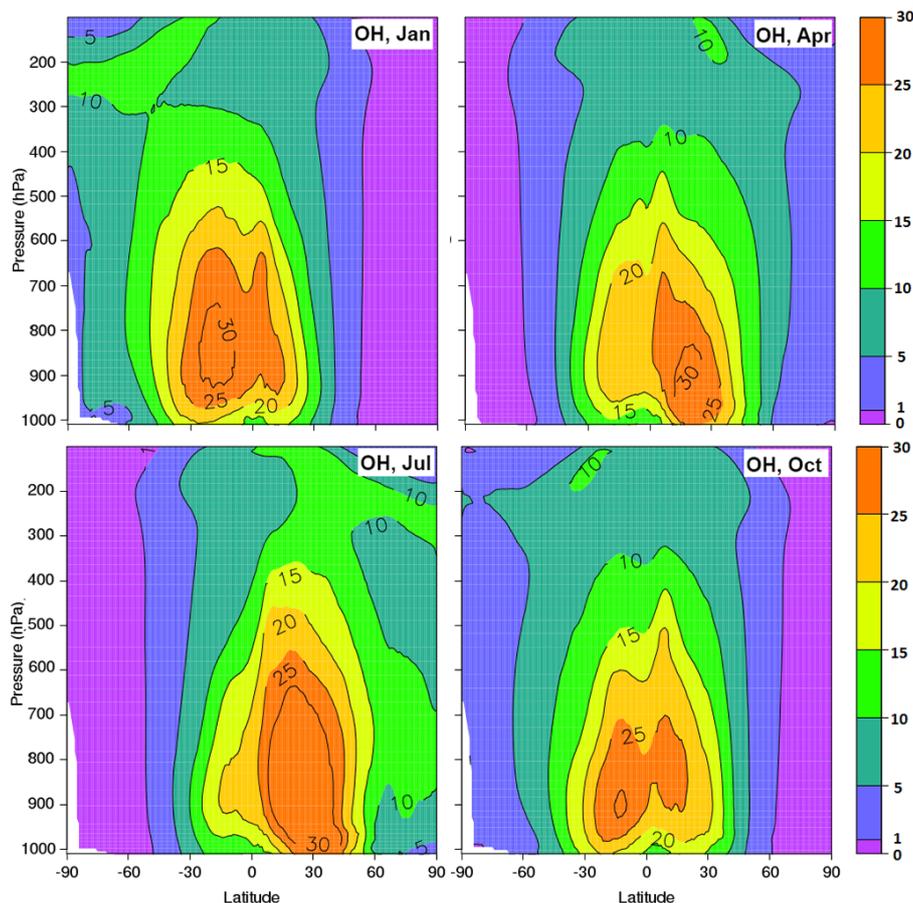

Figure 2. Zonal monthly mean OH concentrations ($10^5 \text{ molec cm}^{-3}$) for January, April, July and October by the NMMB-MONARCH model.

ies (e.g., Horowitz et al., 2003; Huijnen et al., 2010). During January and October the peaks appear in the southern tropics between 700–1000 and 800–1000 hPa, respectively. The peak in April and July is found in the northern tropics between 800–1000 and 700–1000 hPa, respectively.

The mean OH inter-hemispheric (N/S) ratio of the model is 1.18. This quantity is comparable with the present-day multi-model mean ratio (1.28 ± 0.1) shown in Naik et al. (2013b). In addition, the model regional annual mean air mass-weighted OH concentrations have been calculated and are in general agreement with the multi-model values (Naik et al., 2013b) (see Fig. S2). However, concentrations over the tropics ($30^\circ \text{ S} - 30^\circ \text{ N}$) are slightly higher than the multi-model mean and concentrations above 500 hPa are lower than the multi-model mean. Labrador et al. (2004) studied the sensitivity of OH to NO_x from lightning, showing that OH concentrations increase mostly in the middle to upper troposphere (500–200 hPa) if lightning emissions are considered. Therefore, the lack of lightning emissions in our model run could at least partly explain the lower OH values above 500 hPa reported here. Another potential explanation is the lack of aerosols in our simulation, which may overestimate

photolysis rates in polluted regions (e.g., Bian et al., 2003; Real and Sartelet, 2011).

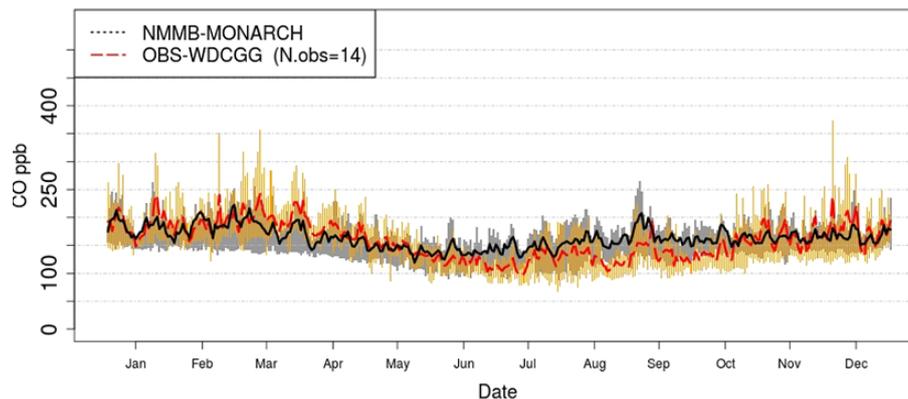

5.2 Carbon monoxide (CO)

CO is one of the most important trace gases in the troposphere, exerting a significant influence upon the concentration of oxidants such as OH and O_3 (Wotawa et al., 2001). The main sources of CO in the troposphere are the photochemical production from the oxidation of hydrocarbons (including methane) and direct emissions, mainly fossil fuel combustion, biomass burning and biogenic emissions. CO main loss is by reaction with OH, which occurs primarily in the tropics, but also in the extratropics.

In the northern extratropics, the elevated CO concentrations are dominated by anthropogenic emissions and precursor hydrocarbons, which leads to a net CO export to the tropics (Shindell et al., 2006; Bergamaschi et al., 2000). Although most of the biomass burning occurs in the tropics, gases and aerosols emitted from large wildfires can be transported to the southern extratropics, where emissions and chemical production are lower. Also, due to strong convec-

Table 6. Annual mean burden of tropospheric CO (Tg CO) in the NMMB-MONARCH, MOZART-2, TM5 and C-IFS global models.

Model	Burden							Reference
	Global	NH	SH	Trop.	N. extratrop.	S. extratrop.	Dry depo.

**Figure 3.** Time series of CO daily mean concentration in ppb averaged over all the rural WDCGG stations used. Observations are depicted with a solid red line and model data with a solid black line. Bars show the 25th–75th quartile interval for observations (orange bars) and the model (gray bars).

tion enhanced by forest fire activity, emissions can reach the upper troposphere and the lower stratosphere (Jost et al., 2004; Cammas et al., 2009). CO has a chemical lifetime of a few months ($\sim 1\text{--}3$), and therefore it is a useful tracer for evaluating transport processes in the model. It is important to keep in mind that despite large Alaskan and Canadian wildfires that occurred during the summer, globally 2004 had lower CO concentrations than other years during the decade (Elguindi et al., 2010).

An analysis of the CO burden in different regions is presented in Table 6. The global and annual mean burden of CO for 2004 is 399.03 Tg, with higher abundances in the tropics (229.43 Tg CO), followed by the northern extratropics (101.71 Tg CO), and the southern extratropics (67.88 Tg CO). Other model estimates of the CO burden (Horowitz et al., 2003; Huijnen et al., 2010; Flemming et al., 2015) are also shown in Table 6. Our estimates are higher by $\sim 46\text{--}48$ Tg CO compared to these studies, and it happens in all regions. The largest absolute difference appears in the tropics where the NMMB-MONARCH predicts $\sim 30\text{--}40$ Tg CO more than these studies, even though OH is also overestimated. The main sources of CO in the tropics are from biomass burning, biogenic emissions and anthropogenic direct emissions of CO.

We performed tests comparing the annual mean burden of tropospheric CO with and without biomass burning emis-

sions in the model. Neglecting biomass burning emissions only reduced 7% of the tropospheric CO annual mean burden. Therefore, other factors should explain our higher CO burden. On the one hand, biogenic emissions are computed online every hour in order to account for evolving meteorological changes such as solar radiation and surface temperature (see Sect. 2.2.6). Also, this simulation neglects the attenuation of radiation due to aerosols, which may produce an overestimation of VOC biogenic emissions and the derived CO.

The CO anthropogenic emissions used in this study ($610.5 \text{ Tg year}^{-1}$) are also higher than those in other inventories (see Sect. 3.1). The dry deposition of CO is significantly weaker in the NMMB-MONARCH (24 Tg CO) than the global model TM5 (184 Tg CO) and the study of Bergamaschi et al. (2000) (292–308 Tg CO). By contrast, other global models such as MOZART-2 have significantly lower dry deposition (2 Tg CO) and the study of Wesely and Hicks (2000) suggests that CO and other relatively inert substances are deposited very slowly. Clearly, there are major uncertainties in the sources and sinks of CO that could be responsible for modeled CO differences.

Figure 3 shows the time series of CO daily mean concentration over 14 ground-monitoring stations from the WDCGG database (primarily in the northern mid-latitudes, but with a few of them in the tropics and southern mid-latitudes).

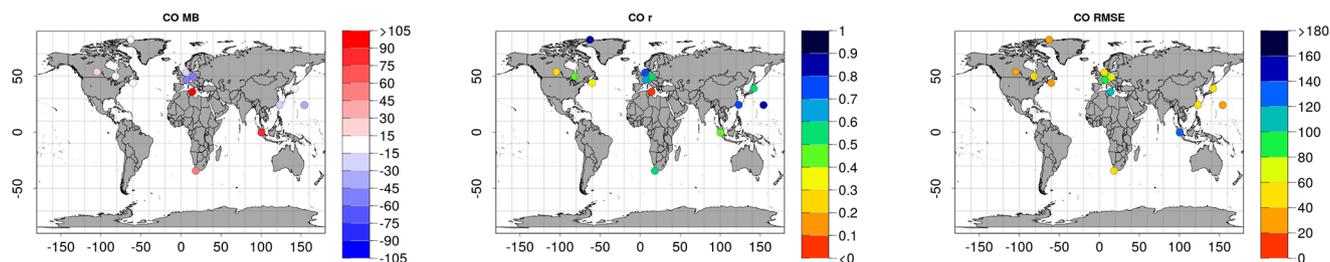

Figure 4. CO spatial distribution of mean bias (MB, ppb) (left panel), correlation (r) (middle panel) and root mean square error (RMSE, ppb) (right panel) at all the rural WDCGG stations used.

The solid red line and the solid black line represent, respectively, the average of observations and the model simulation. Bars show the 25th–75th quartile interval of all observations (orange) and the model simulation (gray). The model is in good agreement with the CO field in the surface layer (daily correlations between 0.3 and 0.7). However, the model is not able to fully capture the seasonal CO variability, with a slight underestimation during cold months (-10.65 ppb) and overestimation during warm months (28.67 ppb). Such a model limitation could be explained by the fact that most of the stations are closer to anthropogenic polluted areas, where its concentration is primarily determined by local emissions, and the CO land-based anthropogenic emissions inventory does not have any seasonal variation in this study (see Sect. 3.1).

Figure 4 shows the CO mean bias (MB), correlation and root mean square error for all rural WDCGG stations. The model has a negative MB over stations in Europe and Japan and a positive bias in stations in Canada and Africa, where the correlations are low. The negative bias for several of the northern mid-latitude stations indicates that the higher CO burden found in our model compared to other models in these areas is a feature mainly driven by free tropospheric abundances. Higher correlations are found in northern regions of Europe, southern Africa and eastern Asian countries. The daily correlation in Canadian stations is between 0.3 and 0.5. In most of the stations, the RMSE is found to be less than 60–40 ppb, with only four stations having a RMSE higher than 60 ppb.

Additionally, the model was compared with seasonally averaged vertical profiles of temporally collocated CO from MOZAIC aircraft observations from selected airports: Frankfurt, Beijing, Atlanta, Portland, Abu Dhabi and Niamey (shown in Figs. 5 and S3). Observations and model results (both mean and standard deviation) are represented in red and black, respectively. We note that the number of flights differ among airports (therefore not all comparisons are statistically robust), and the CO range represented for Beijing is larger (0–1000 ppb) than for other stations (0–400 ppb). The model captures reasonably well the vertical profiles during the first part of the year and shows larger biases during the warm months. It overestimates CO from the mid-

dle to the upper troposphere in most stations throughout the year. Over Frankfurt, the model is in good agreement with the observations during the entire year, despite slight underestimations during MAM (~ -31 ppb) and overestimations during SON (~ 12 ppb) in the middle troposphere. For Beijing, one of the most polluted cities in the world, the model shows a clear tendency to underestimate CO in the lower atmosphere (below 600 hPa). This is very probably due to an underestimation of CO anthropogenic emissions. Most AQMs are unable to capture the extreme growth of anthropogenic emissions in China (Akimoto, 2003; Turquety et al., 2008). Over Atlanta, the model performs better in winter and spring throughout the troposphere than in summer and autumn, when positive biases reach ~ 20 – 25 ppb. In regions with biomass burning and biogenic influence, such as Abu Dhabi and Niamey, the model significantly overestimates CO during warm months throughout the tropospheric column. During winter and spring, Stein et al. (2014) also obtain an underestimation of CO vertical profiles in airports located in the Northern Hemisphere (NH).

To complete this CO evaluation, seasonal averages are compared with data from the MOPITT instrument at 800 and 500 hPa (Figs. 6 and S4, respectively). At 800 hPa, the largest differences are detected during boreal winter and spring, when the model clearly overestimates in the tropics and underestimates in the northern extratropics and northern Africa. The wintertime negative bias (~ -10 – 35 ppb) in the NH may be explained by either the lack of seasonally varying anthropogenic emissions in our simulation, an underestimation of CO emissions (Stein et al., 2014), or a combination thereof. There are significant positive biases over western-central Africa, western South America, Indonesia and the surrounding Pacific and Indian oceans during the dry season. Sources of CO over western-central Africa are mainly from biomass burning and biogenic emissions. Uncertainties in the emission inventories probably contribute to the CO overestimation in these regions. Due to the long-range transport of CO, higher concentrations are also seen throughout the year over the tropics and some parts of the extratropics from June to November. During JJA and SON the model overestimates CO in most places, including southern and central Europe and the US (~ 10 – 25 ppb). At 500 hPa, the model presents

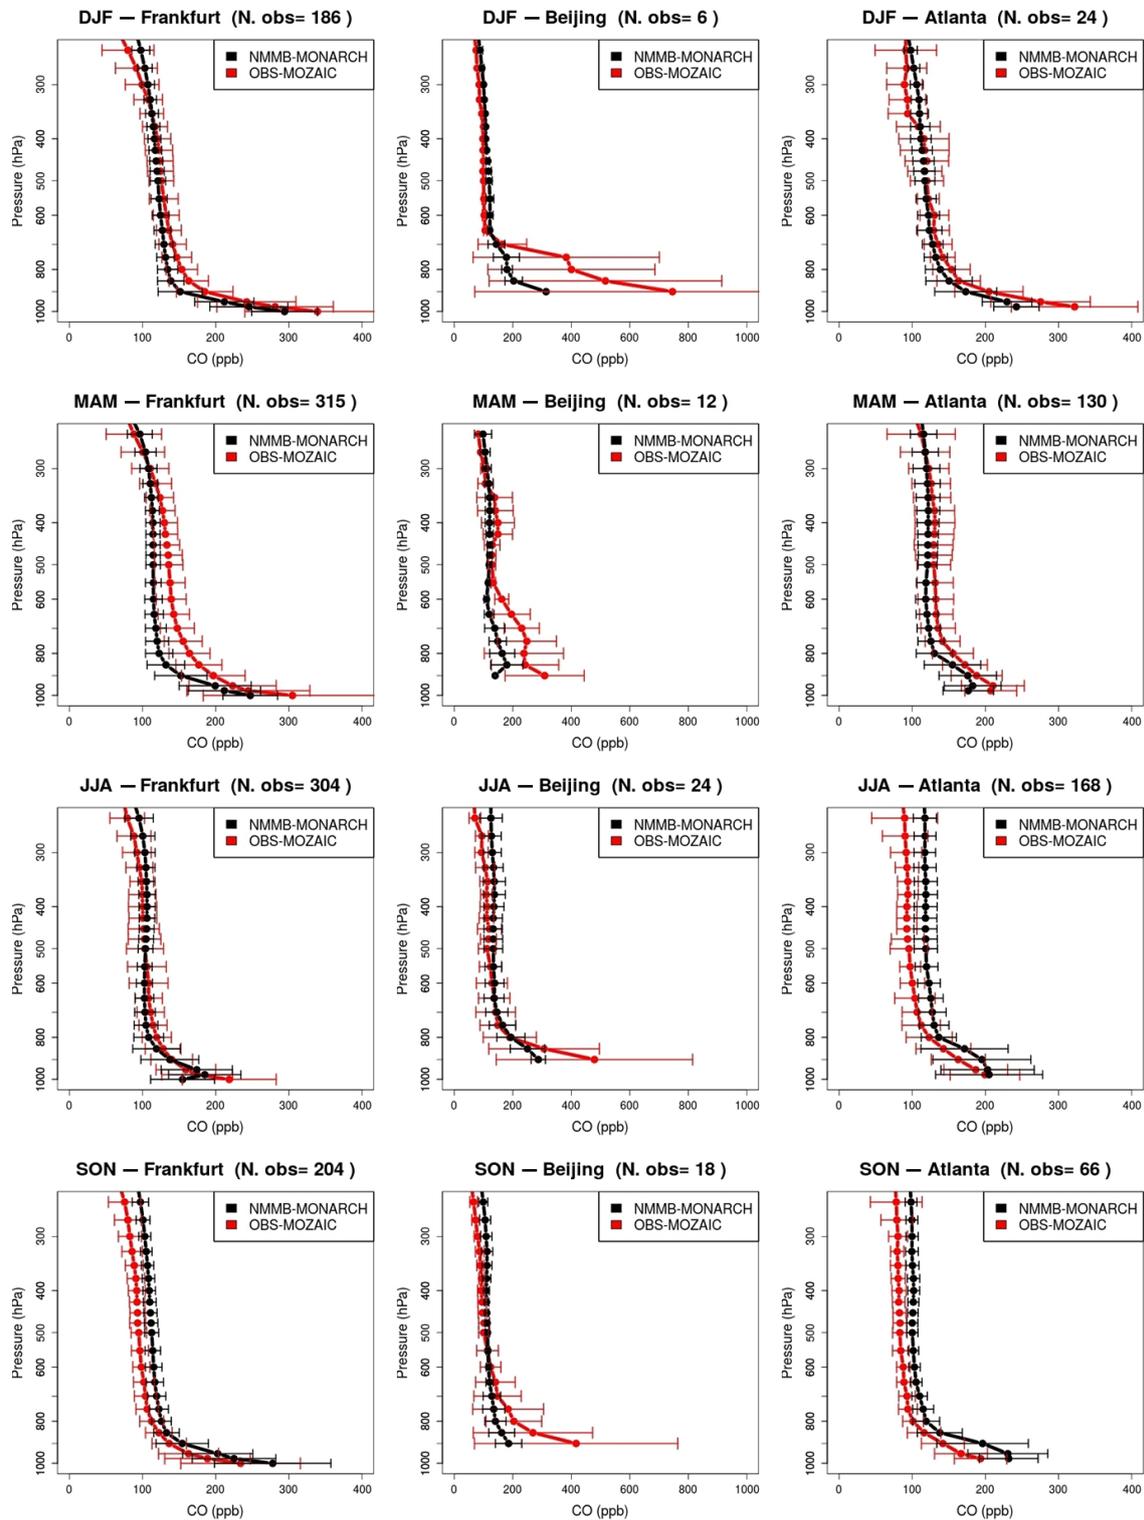

Figure 5. CO vertical profile seasonal averages over Frankfurt, Beijing and Atlanta (from left to right) for the year 2004 from MOZAIC. Observations depicted with a solid red line and the model with a solid black line. Horizontal lines show the standard deviations. The number of flights is provided on the top of each plot.

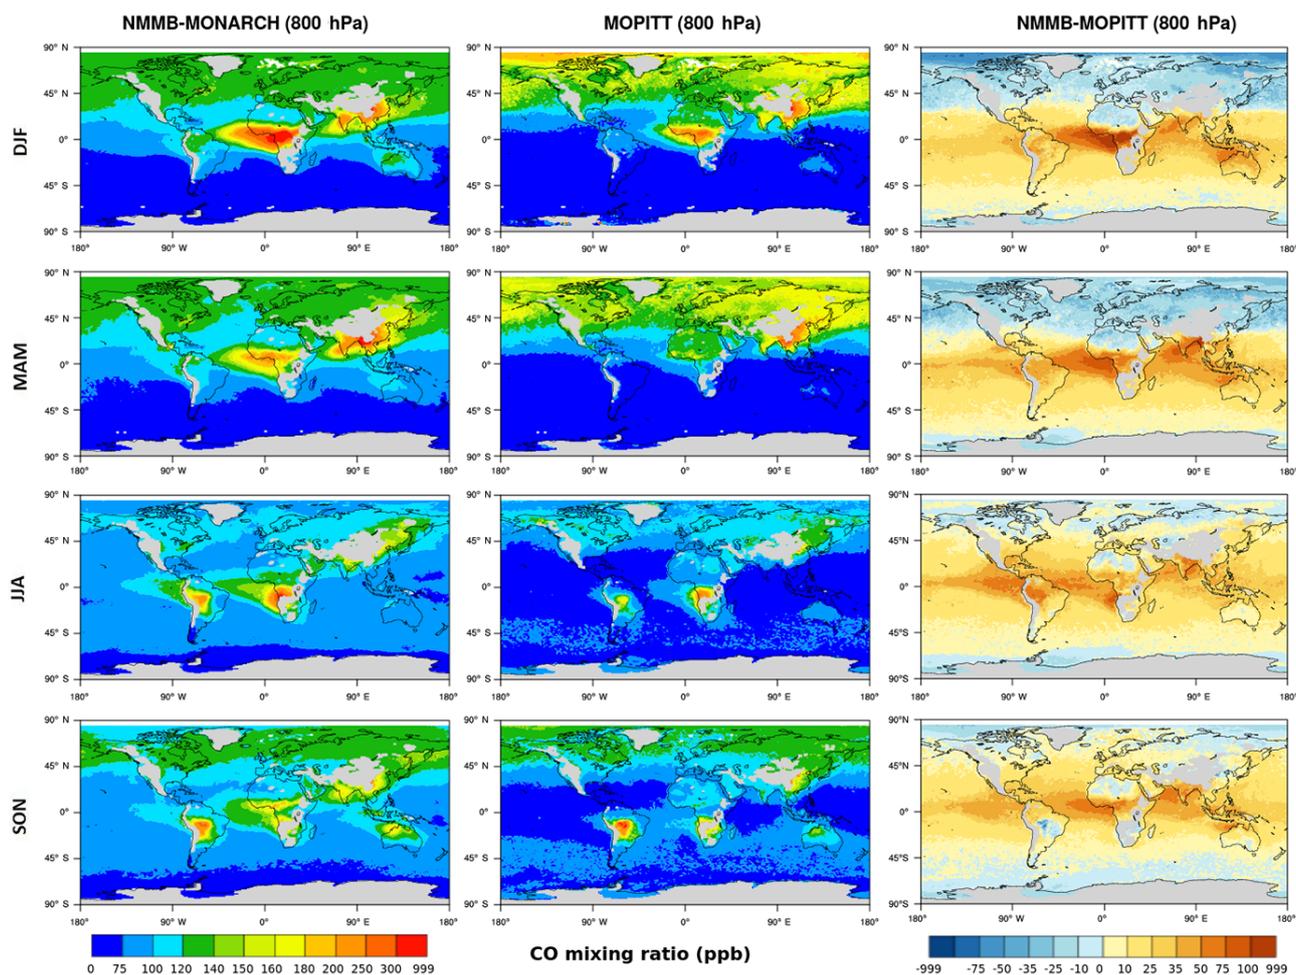

Figure 6. Comparison of the modeled CO mixing ratio at 800 hPa against satellite data (MOPITT) in ppb. From top to bottom: DJF for December–January–February, MAM for March–April–May, JJA for June–July–August and SON for September–October–November for the year 2004. NMMB-MONARCH data are displayed in the left panel, MOPITT data in the middle panel, and the bias in the right panel.

similar results, with clear underestimations in the northern extratropics and overestimations in the tropics and southern latitudes. Excessive vertical mixing by moist convection may explain the overestimation in the tropics. Overestimated emissions in Africa or Asia above the PBL could also lead to this positive bias in the middle of the troposphere.

Naik et al. (2013b) compared the multi-model annual mean from 17 models for the year 2000 with the average CO from MOPITT at 500 hPa between 2000 and 2006. The 17 models used the same anthropogenic and biomass burning emissions as our model, and a priori and averaging kernels were taken into account for each model before computing the biases. The biases in the tropics and extratropics are similar to those presented here, suggesting systematic model errors due to inaccurate anthropogenic and biomass burning emission inventories. We note that MOPITT V4 CO retrievals are affected by biases of about -6% at 400 hPa when evaluated with in situ measurements (Deeter et al., 2010), which are low compared to current model discrepancies. Naik et al.

(2013b) also discussed how an overestimated OH concentration may lead to the northern mid-latitude underestimation of CO. This may partly explain our results given the higher OH concentration simulated by our model compared to other models. Numerous studies show significant differences in CO among AQMs, which may emerge from a variety of uncertainties, including those in emission inventories and injection heights (Elguindi et al., 2010; Shindell et al., 2006; Prather et al., 2001). For example, Stein et al. (2014) suggest that the persistent negative bias in northern mid-latitude CO in models is most likely due to a combination of too low road traffic emissions and dry-deposition errors.

5.3 Nitrogen compounds

The $\text{NO}_x (= \text{NO}_2 + \text{NO})$ family is one of the key players in the formation of O_3 in the troposphere, causing photochemical smog and contributing to acid rain during pollution episodes. Because it has a relatively short lifetime (a few

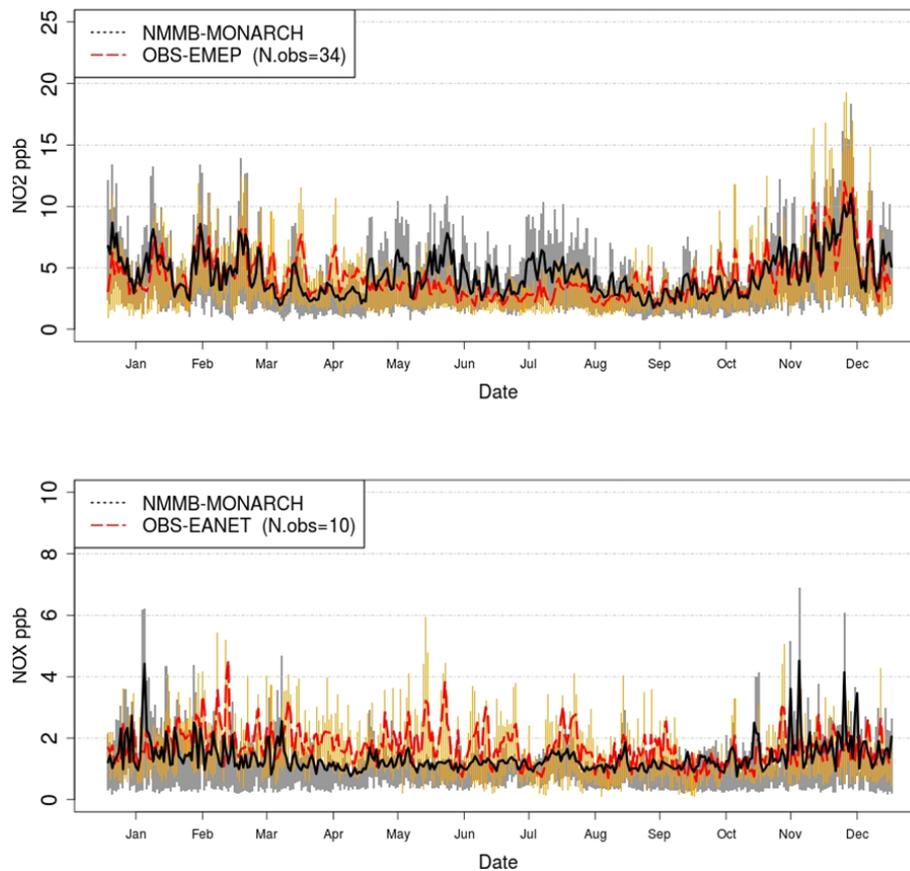

Figure 7. Time series of NO_2 (top) and NO_x (bottom) daily mean concentration averaged over the rural EMEP and EANET stations, respectively, in ppb. Observations are depicted with a solid red line and model data with a solid black line. Bars indicate the 25th–75th quartile interval for observations (orange bars) and model (gray bars).

hours within the PBL and up to a few days in the upper troposphere; Tie et al., 2001, 2002), it is generally restricted to emission sources, both natural and anthropogenic (mainly fossil fuel combustion). The seasonal cycle of NO_x near the surface is controlled by the seasonality of anthropogenic emissions (especially in the NH) and biomass burning emissions (especially in the tropics and the Southern Hemisphere (SH)). As a result, NO_x concentration is more sensitive to errors in emissions than other pollutants (Miyazaki et al., 2012).

Figure 7 shows the time series of NO_2 and NO_x daily mean surface concentrations over 21 EMEP and 10 EANET rural ground-monitoring stations. In both cases the model is able to successfully reproduce the seasonal cycle of NO_2 and NO_x . However, a positive bias (< 3 ppb) is found during summertime for NO_2 in Europe (Fig. 7, top panel), which may result from the lack of seasonality in the anthropogenic emissions. The modeled NO_2 concentration is excessive during nighttime (not shown). This may result from the lack of heterogeneous formation of HNO_3 through N_2O_5 hydrolysis, an important sink of NO_2 at night. In addition, the model does not consider secondary aerosol formation in the

present study, resulting in an excessively oxidizing atmosphere (overestimation of OH radicals) that in turn may lead to an accumulation of NO_2 near the surface. Between 09:00 and 18:00 UTC there is a slight underestimation of NO_2 . In Asia (Fig. 7 bottom) the model does not reproduce the observed NO_x values, showing a large negative bias during the summer probably due to underestimated emissions (Akimoto, 2003; Richter et al., 2005), as in the case of CO. Also, an excessive mixing within the PBL during the night could contribute to a decrease in ozone titration by NO and explain the bias.

The model correlation is lower in regions such as the Iberian Peninsula and most of the stations in Japan (Fig. 8). The best performance occurs in central Europe and stations in Japan that are not in the main island. In general there is a negative bias in most of the stations for these two regions.

Figure 9 displays the comparison of NO_x , HNO_3 and PAN vertical profiles for several regions in the US, China, Hawaii and Japan (see Table 5). The comparison over Tahiti and Ireland is shown in Fig. S5. As explained in Sect. 4.2, the observed vertical profiles do not correspond to the simulated year (see Table 5 for more details), but the qualitative patterns

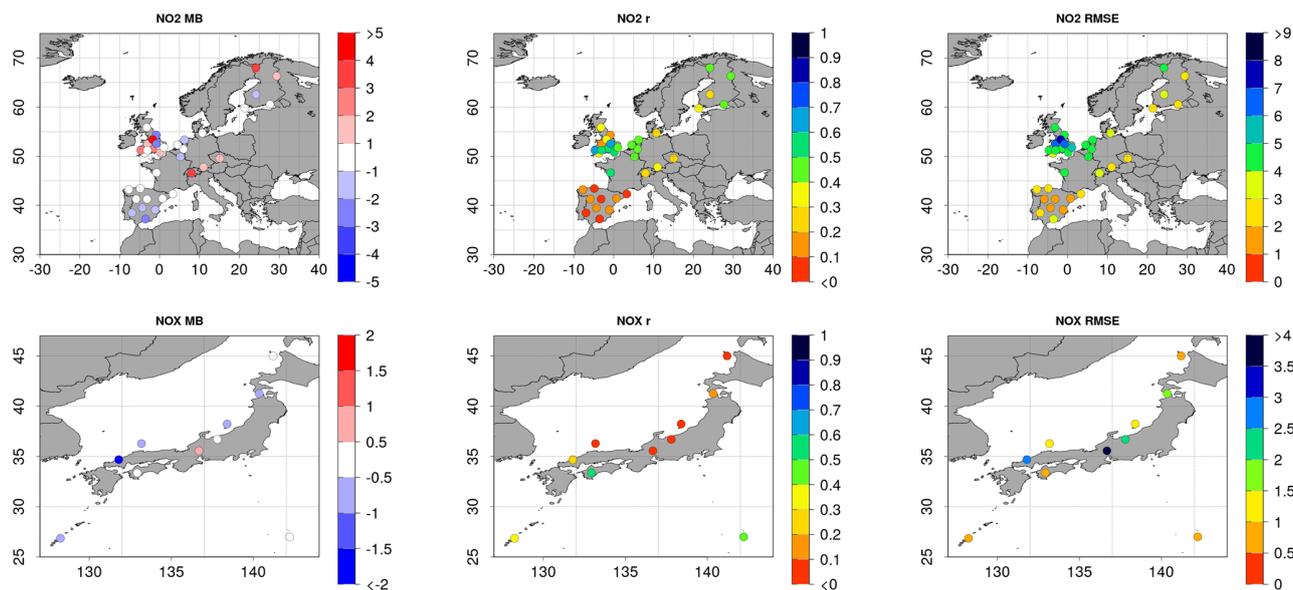

Figure 8. NO₂ (top) NO_x (bottom) and spatial distribution of mean bias (MB, ppb) (left panel), correlation (r) (middle panel) and RMSE (ppb) (right panel) at all rural EMEP and EANET stations, respectively.

can provide insights on the model capability to reproduce the chemistry involved. Figure 9 (first column) shows that vertical profiles of NO_x are really well captured by the model. The model has a tendency to overestimate NO_x concentrations near the surface (~ 400 ppt in Japan and ~ 300 ppt in China); it is likely that NO_x emissions used in this study are higher than the actual emissions during the campaign periods. Another reason for these higher values over island locations (Japan and Hawaii) could be that emissions are spread over the coarse model grid box while the measurements were taken in the cleaner marine boundary layer. In the middle and upper troposphere, the model produces the concentrations well, with a slight underestimation in most of the locations. Note that NO_x lightning emissions are not included in this simulation, which may explain part of this underestimation, particularly in the upper troposphere.

PAN is the main tropospheric reservoir species for NO_x with important implications for the tropospheric O₃ production and the main atmospheric oxidant, OH (Singh and Hanst, 1981). PAN is mainly formed in the boundary layer by oxidation of NMVOCs in the presence of NO_x. NMVOCs and NO_x have both natural and anthropogenic sources. Rapid convection can transport PAN to the middle and upper troposphere and enables the long-range transport of NO_x away from the urban and polluted areas, where it can produce O₃ and OH remotely.

Some features of the vertical profiles are well captured by the model, although it significantly overestimates PAN concentrations (see Fig. 9, third column). We find overestimations from the surface to the middle atmosphere in Japan, China, Boulder and Churchill, which are possibly explained

by an overestimation of biogenic and anthropogenic NO_x surface emissions. Another possibility for this overestimation is an excessive lifetime of PAN. In most sites, the modeled PAN concentration tends to increase with altitude, reaching maximum mixing ratios at about 6 km, from where it progressively decreases. This behavior explains the long thermal decomposition time of PAN (lifetime of approximately a month) and the slow loss by photolysis in the cold middle-upper troposphere. Fischer et al. (2014) analyze the sensitivity of PAN to different emission types, showing that most of the NH and Japan are more sensitive to anthropogenic emissions, while the SH and the western coast of the US are more sensitive to biogenic emissions, both contributing 70–90 % of the PAN concentrations.

HNO₃ is mainly produced by the reactions of NO₂ with OH and by the heterogeneous hydrolysis of N₂O₅ (we do not account for the latter in this simulation), and removed by wet and dry deposition. HNO₃ is the main sink of NO_x chemistry. In general, the modeled and observed nitric acid concentrations are of the same magnitude throughout the troposphere, although the model tends to overestimate HNO₃ concentrations, particularly in US regions. In the regions of Hawaii, Japan and China the model overestimates HNO₃ in the lower-middle troposphere (up to 5 km) and underestimates it in the upper troposphere (above 6 km). Overestimation of HNO₃ in the troposphere is a common problem in global models (Hauglustaine et al., 1998; Bey et al., 2001; Park et al., 2004; Folberth et al., 2006). HNO₃ concentrations are highly sensitive to the parameterization of wet deposition. One possible reason for this overestimation is that the scavenging from convective precipitation is underestimated.

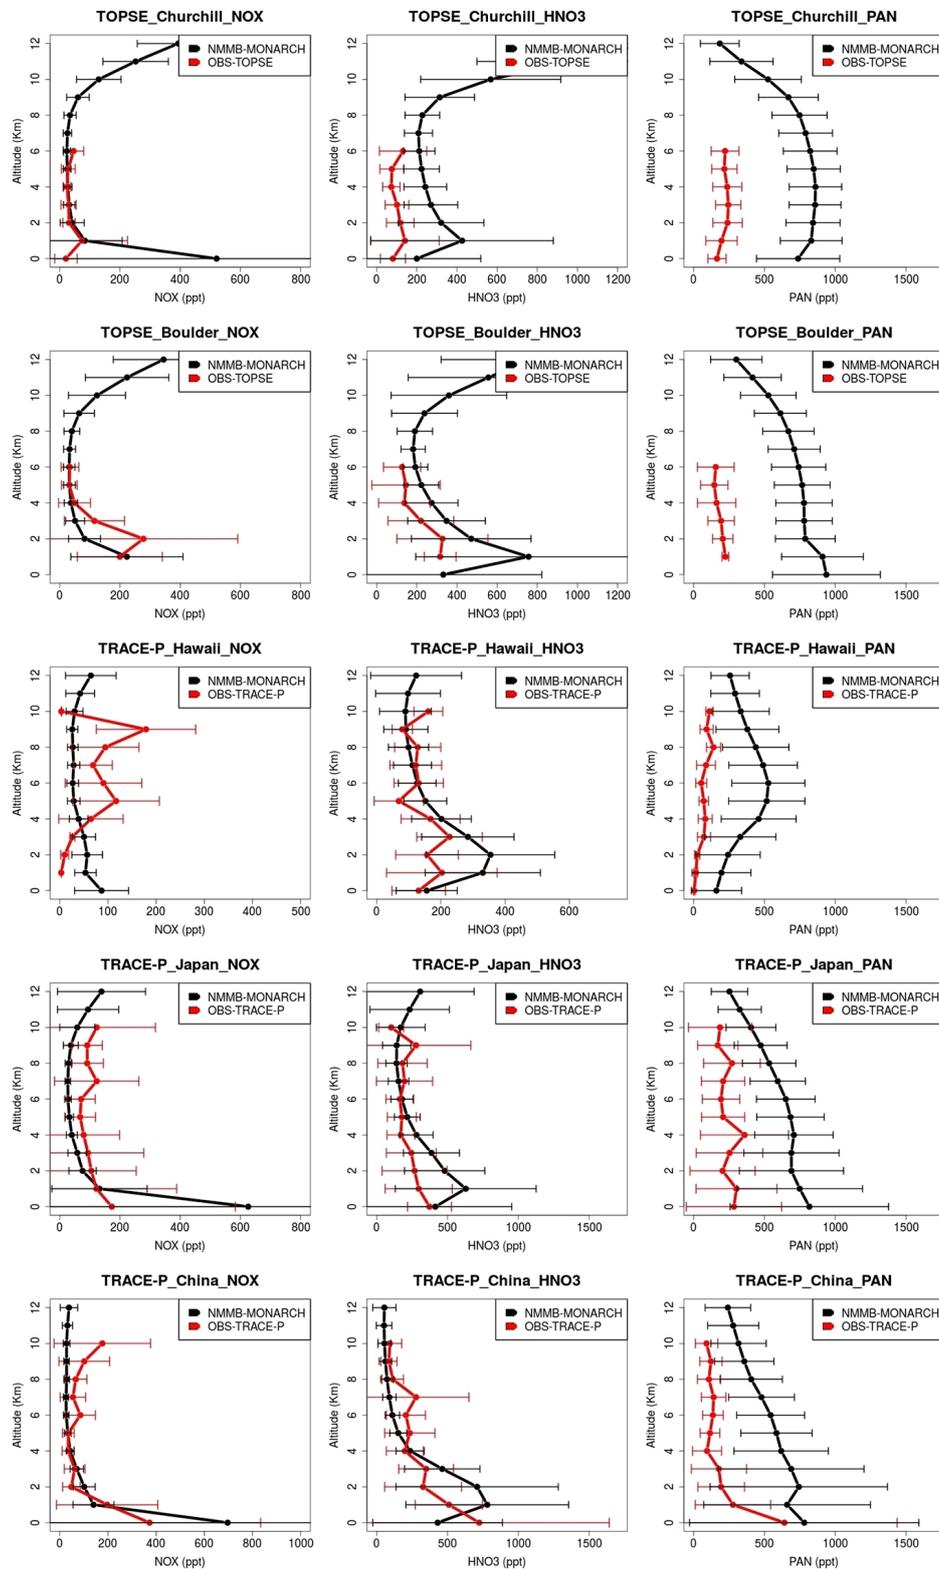

Figure 9. Comparison of modeled (black lines) and observed (red lines) vertical profiles of NO_x (first column), HNO_3 (second column) and PAN (third column) for several regions in the US, China, Hawaii and Japan. Horizontal lines show the standard deviations.

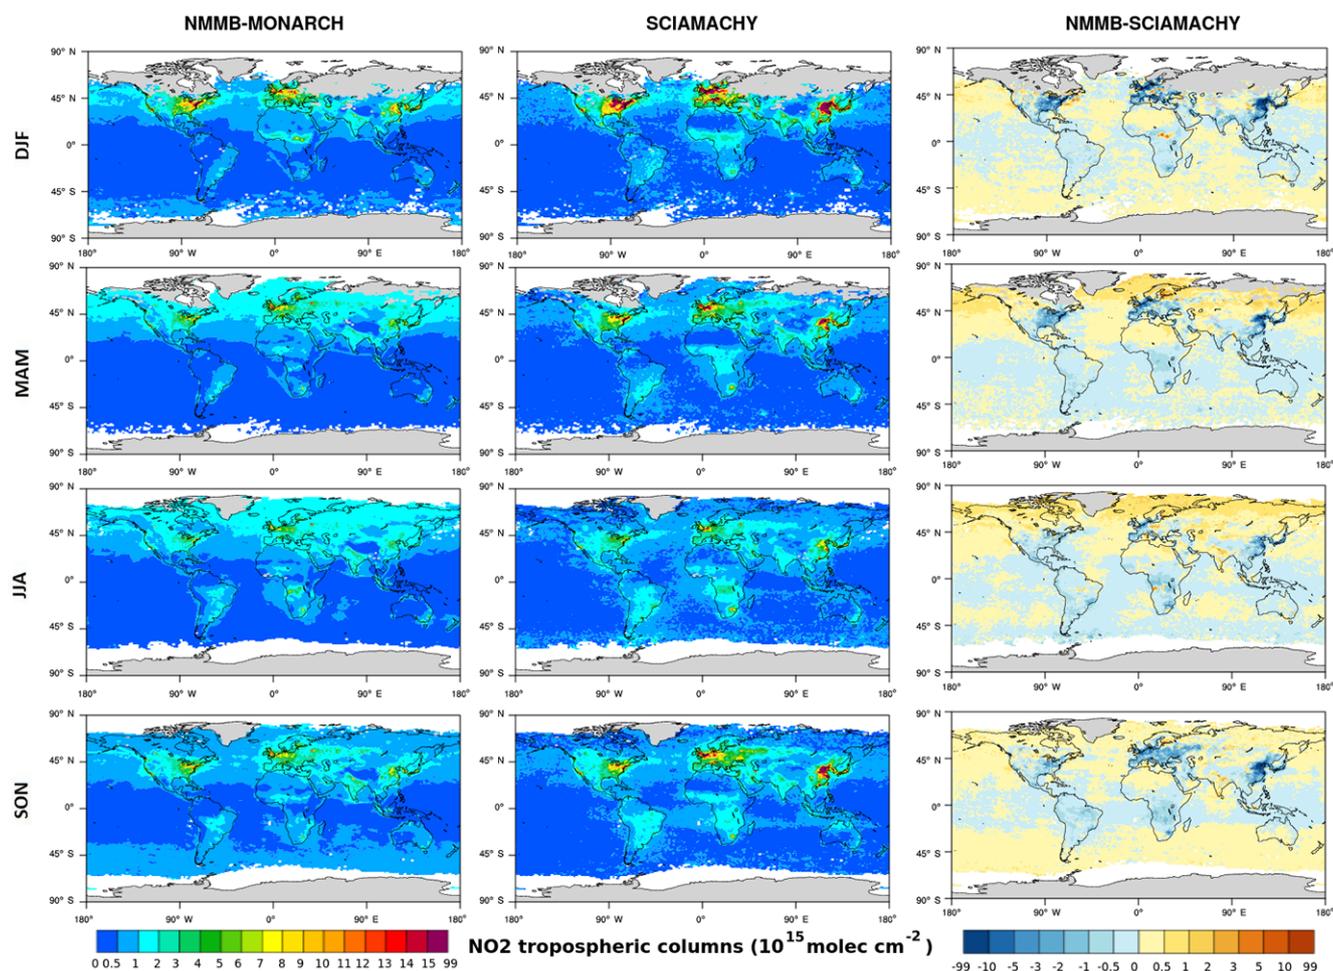

Figure 10. Comparison of modeled NMMB-MONARCH NO_2 vertical tropospheric columns against satellite data (SCIAMACHY) in $10^{15} \text{ molec cm}^{-2}$. From top to bottom: DJF, MAM, JJA, and SON for year 2004. NMMB-MONARCH data are displayed in the left panel, SCIAMACHY data in the middle panel and the bias in the right panel.

Figure S6 evaluates the wet deposition fluxes of HNO_3 with nitrate observations in Europe, the US and Asia. Satisfactory agreement is found in the HNO_3 wet deposition fluxes, with correlations of 0.63 in Europe, 0.80 in the US and 0.52 in Asia. There is a tendency to underestimate in most of the stations, mainly in Asia ($\text{MB} = -163.27 \text{ mg N m}^{-2}$) and Europe ($\text{MB} = -200.70 \text{ mg N m}^{-2}$). We note that these observations include particulate nitrate in addition to HNO_3 , and our model omitted nitrate in this study. Therefore, while the underestimation may be partly due to this omission, it is consistent with the higher values of HNO_3 observed in the lower and middle troposphere.

Seasonal averages of vertical tropospheric columns (VTCs) of NO_2 are compared with SCIAMACHY satellite data in Fig. 10. The model is in line with the observations, capturing the high NO_2 values over the most polluted regions, such as Europe, the US and eastern Asia. The phase in the seasonal cycle of the NO_2 columns is captured satisfactorily by the model. Throughout the year, the

model tends to underestimate NO_2 VTCs in megacities, especially during the colder months, and overestimate them in rural regions. The largest discrepancies are seen in eastern China, which suggests an underestimation of emissions regionally. The biomass burning cycle is captured remarkably well, with higher NO_2 VTCs in central Africa during DJF and in South America in JJA. The model does really well over the ocean, where only small biases are detected ($\pm 0.5 \times 10^{15} \text{ molec cm}^{-2}$).

5.4 Ozone (O_3)

Tropospheric O_3 is originated from in situ photochemical production and stratospheric intrusions. Its photochemical production involves the oxidation of CO and hydrocarbons in the presence of NO_x and sunlight. In remote areas, CO and CH_4 are the most important species oxidized during O_3 formation. In polluted areas, short-lived NMVOCs (e.g., HCHO) are present in high concentra-

Table 7. Annual mean burden, dry deposition of tropospheric O₃ and stratospheric inflow (Tg O₃) for the NMMB-MONARCH, MOZART-2, TM5, LMDz-INCA, GFDL AM3, and C-IFS global models, and two different multi-model ensembles (including 25 and 15 global models each).

tions and are the most important species. The simulated global burden of tropospheric O₃ is shown in Table 7. O₃ chemical sources and sinks are dominated by the tropics (171.60 Tg O₃). Lower values are predicted in the northern extratropics (101.56 Tg O₃) and especially in the southern extratropics (75.41 Tg O₃), where the presence of precursors is limited. Similar results are found in other global models such as MOZART-2 (Horowitz et al., 2003) and TM5 (Huijnen et al., 2010), with MOZART-2 having a higher and TM5 a lower global burden than our model, and both a lower burden in the southern extratropics (by 10–14 Tg O₃). Higher CO concentrations in the SH (see Table 6) might lead to excessive production of O₃ in this region. Our global tropospheric O₃ burden (348 Tg O₃) is also in good agreement with the C-IFS global model (Flemming et al., 2015), the GFDL AM3 chemistry–climate model (Naik et al., 2013a) and multi-model means (Stevenson et al., 2006; Young et al., 2013).

According to our calculations, 1201 Tg O₃ are removed from the troposphere by dry deposition, a value well above TM5 (829 Tg O₃) and MOZART-2 (857 Tg O₃) estimates, but in agreement with LMDz-INCA (1261 Tg O₃), GFDL AM3 (1205 ± 20) and the multi-model ensemble study by Stevenson et al. (2006) (1003 ± 200 Tg O₃). The net stratospheric input, stratosphere–troposphere exchange (STE), annual rate of the model (384 Tg O₃) is also shown in Table 7. STE exchange flux is calculated as the annual balance of the ozone mass crossing the 100 hPa height. The model’s STE is in good agreement with other modeling studies, especially with the multi-model ensemble in Stevenson et al. (2006) (552 ± 168 Tg O₃).

Figure 11 shows the time series of O₃ daily mean concentration averaged over all available monitoring sites (from top to bottom, WDCGG, CASTNET, EMEP and EANET) over the entire simulation period. The solid red line and solid black line represent the average of observations and the model, respectively. Bars show the 25th–75th quartile interval of all observations (orange) and model simulation (gray). There is an overall good performance, although there

is significant positive bias from May to October in the US and Japan. The modeled seasonal cycle agrees well with the observations, showing the highest concentrations during July–August and the lowest ones during November–December. Although the model captures the seasonal variability, it shows a tendency to overestimate concentrations during the warmer months, i.e., May–September. This positive bias is significantly higher in the US, where the overestimation occurs throughout the year (5–15 ppb). Over Europe, the overestimation during summer is lower than in other regions. Over eastern Asia the model captures reasonably well the peaks in April and May, although it is positively biased during the rest of the year, overestimating during the cold months in contrast to Europe where the model agrees with the observations. Overall the observational networks show a reduction of O₃ from May to June, but the model has a tendency to simulate an annual cycle with higher concentrations until July. Possible reasons for the overestimation could be the reduction of the ozone titration due to an excessive emission injection height prescribed in the model, or the dry-deposition processes included in our model. Val Martin et al. (2014) show that accurate dry-deposition processes can reduce the summertime surface O₃ bias from 30 to 14 ppb and from 13 to 5 ppb over the eastern US and Europe, respectively. Further investigation is required to understand model behavior during this period.

Figure 12 displays the spatial statistics for O₃ over all in situ monitoring sites using daily mean data. Areas without emissions such as the South Pole and isolated islands in the tropics show small mean biases and root mean square errors, and good correlations (> 0.80). In polluted areas, a good performance is observed in the US midlands and parts of central and southern Europe (0.60 < *r* < 0.80 and RMSE < 12 ppb). Large errors are seen in the northwestern and southern US and northern Europe. Although large errors are seen in all the stations over Japan, the two more distant stations from the main island show high correlation (*r* > 0.7).

In order to assess the vertical distribution of O₃, the model results are compared with available ozonesondes in Figs. 13

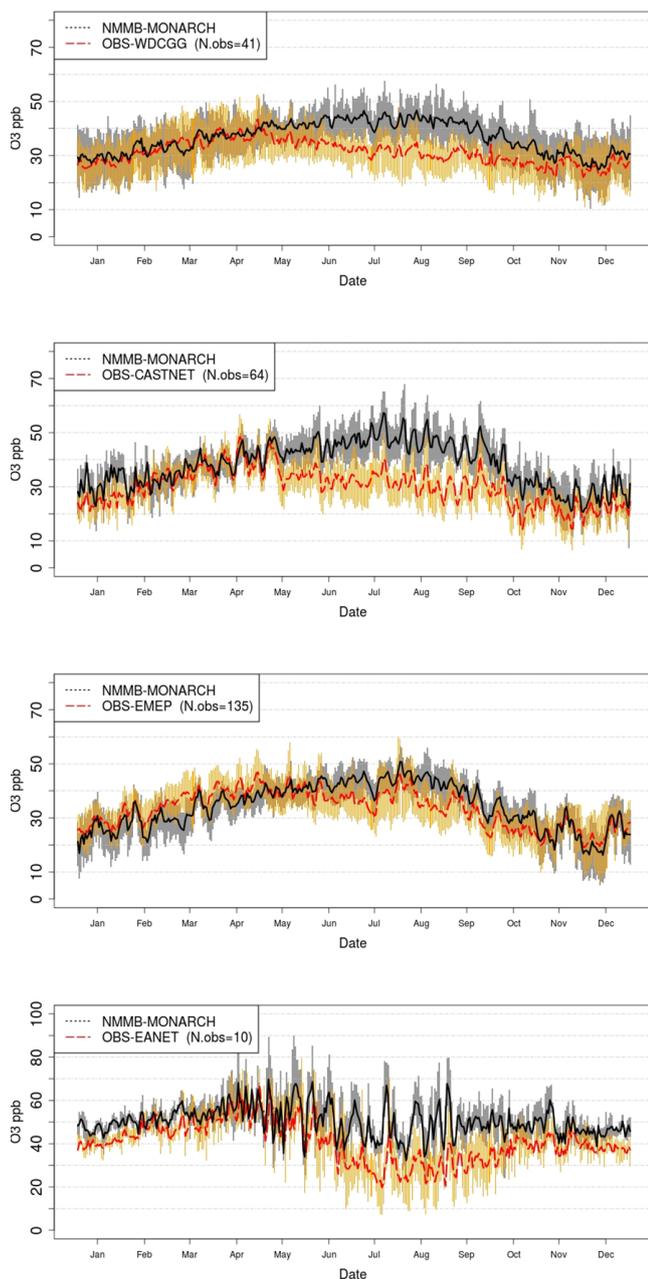

Figure 11. Time series of O₃ daily mean concentration averaged over rural WDCGG, CASTNET, EMEP and EANET stations (from top to bottom) in ppb. Observations are depicted with a solid red line and model data with a solid black line. Bars indicate the 25th–75th quartile interval for observations (orange bars) and model (gray bars).

and S7 during the study period (see Table 3 and Fig. 1 for more details). The figures show (from top to bottom) four panels: DJF, MAM, JJA and SON for each region. Measurements are represented by the solid red line and the model results by the solid black line. The variability of the data is shown in the form of standard deviation for both the model

and the observations. The magnitude and vertical profile are consistent with the observations. However, the model shows a positive bias of ~ 5 – 20 ppb along the troposphere in most of the regions throughout the year. As shown in Sect. 5.2 there is a significant overestimation of CO, especially in the free troposphere for some regions, which may account for the positive O₃ biases, although the CO overestimation mostly occurs in the tropics where O₃ biases are not so large. Another reason for this result could be that anthropogenic aerosols and secondary aerosol formation are neglected in this simulation, leading to a higher O₃ formation in regions with more precursors. However, this should have more localized effects and therefore it cannot fully explain the biases throughout the troposphere. Possible biases in the stratospheric O₃ or the lack of other specific chemistry (e.g., halogen chemistry) could also contribute to this positive bias.

The vertical profile is in good agreement with the observations, with O₃ increasing from the lower to higher tropospheric layers. In the lower–middle troposphere the model overestimates O₃ in regions with high emissions (Japan, Canada, the US and western Europe), a feature that stands out in DJF (< 20 ppb). In western Europe and the US, this bias is reduced at the surface level. In tropical areas (Equator, NH tropical and western Pacific) the model captures well the observed concentration and vertical structure of O₃ in the lower to middle troposphere. However, the model tends to overestimate the O₃ in the vicinity of the tropopause layer in these regions (10–20 ppb). At polar regions (NH and SH Polar) the model also presents a tendency to overestimate the vertical structure of O₃. O₃ in the tropopause layer is underestimated in the NH Polar case and overestimated in the SH Polar case.

Finally, statistics were computed to identify those areas where the errors are more important. Figure 14 shows the mean O₃ bias (left), correlation (middle) and RMSE (right) of the model with respect to ozonesondes (data are averaged between 400 and 1000 hPa). As we have shown, the mean bias is positive for most stations (MB < 30 ppb). Large RMSEs are seen in northern high latitudes (< 50 ppb) and in two stations from the US. Europe and Japan present an RMSE around 30 ppb and the tropics and subtropics are regions with lower errors, i.e., RMSE below 30 ppb. The highest correlations are seen in polar regions.

6 Conclusions

We provided a comprehensive description and evaluation of the gas-phase chemistry component of the NMMB-MONARCH model version 1.0 at global scale. The model considers 51 chemical species, solves 156 reactions, and simulates the global distributions of ozone and its precursors, including CO, NO_x, and VOCs. The simulation presented here was configured with a horizontal resolution of $1.4^\circ \times 1^\circ$, 64 vertical layers and a top of the atmosphere at

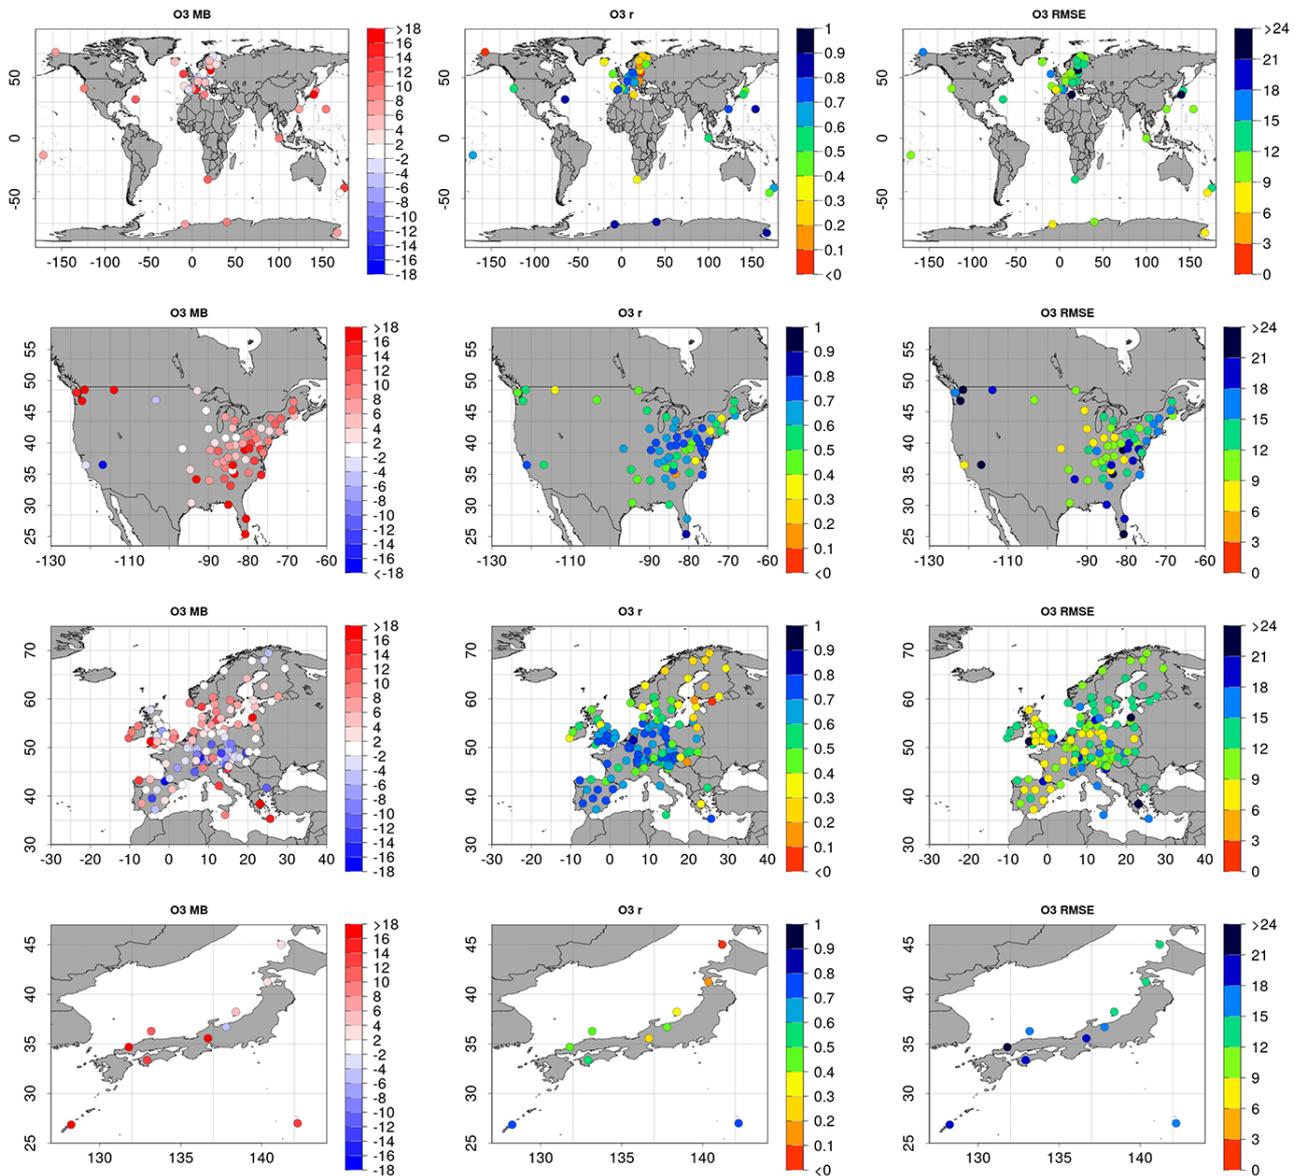

Figure 12. Spatial distribution of the O₃ mean bias (MB, ppb) (left panel), correlation (r) (middle panel) and RMSE (ppb) (right panel) at rural WDCGG, CASTNET, EMEP and EANET stations (from top to bottom).

1 hPa. Modeled tropospheric ozone and related tracers were evaluated for year 2004 using data from surface-monitoring stations, ozonesondes, satellite and aircraft campaigns. We used emissions from ACCMIP (Lamarque et al., 2010) for fossil fuel combustion, biofuel, biomass burning, soil and oceanic emissions. Biogenic emissions are calculated online with the MEGANv2.04 model (Guenther et al., 2006). We note that in this contribution, we omitted aerosols and lightning emissions; anthropogenic emissions disregard seasonality; and biomass burning emissions are not specific to 2004.

The evaluation of OH concentrations is in agreement with previous studies (Spivakovsky et al., 2000; Voulgarakis et al., 2013). The OH peak concentrations occurring in April and

July at northern latitudes are slightly higher than the climatological mean calculated in Spivakovsky et al. (2000). Neglecting anthropogenic aerosols and secondary aerosol formation may be leading to a more oxidized atmosphere due to higher photolysis rates. However, overall, the widespread positive ozone biases identified seem to be responsible for the higher OH concentrations.

The global annual mean burden of CO (399 Tg) is higher than in other studies, with larger concentrations located in the tropics (229.43 Tg CO). The model is in relatively good agreement with CO observations at the surface (daily correlations between 0.3 and 0.7), and shows negative biases at stations over Europe and Japan, and positive biases in Canada

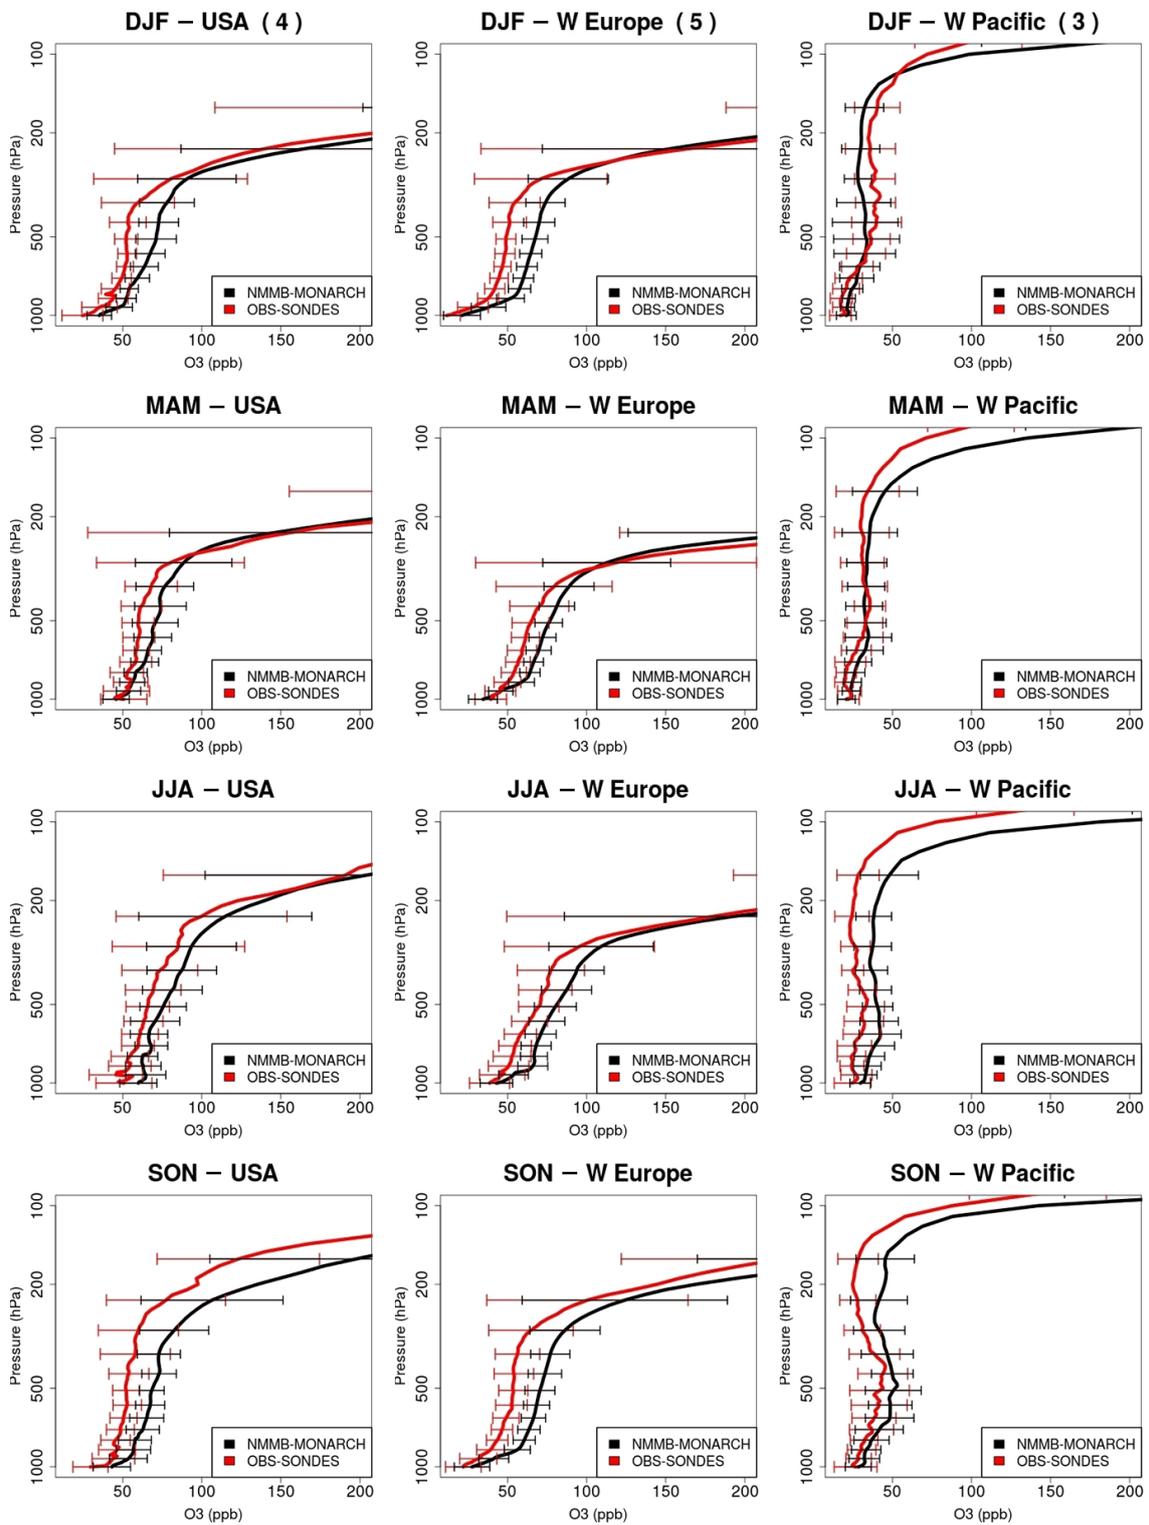

Figure 13. Comparison of ozonesonde measurements (red lines) and simulated (black lines) seasonal vertical profiles of O₃ (ppb) and standard deviations (horizontal lines). The region name and the number of stations are given above each plot between brackets.

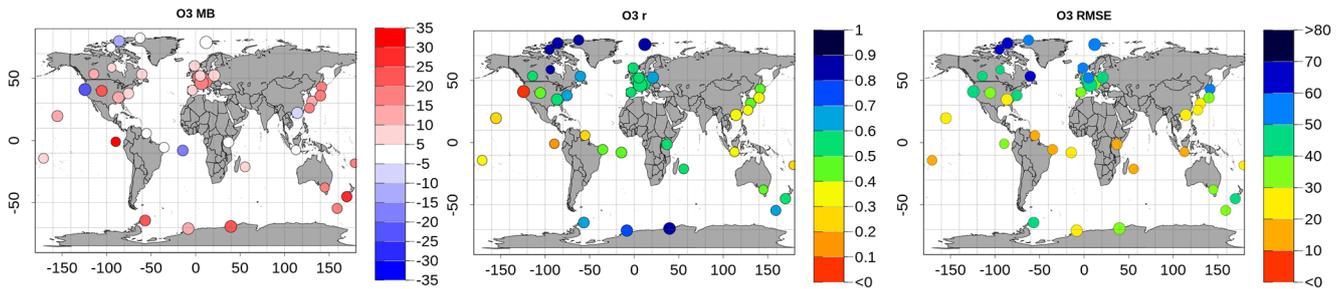

Figure 14. Mean tropospheric ozone bias spatial distribution (MB, ppb) (left panel), correlation (middle panel) and RMSE (ppb) (right panel) for year 2004, averaged between 400 and 1000 hPa. The diameter of the circles indicates the number of profiles over the respective stations. The bias is calculated as model minus observation.

and Africa. The largest correlations are found in northern Europe, southern Africa and eastern Asia. Concerning the vertical structure of CO, the model presents a good performance during the DJF and MAM, while positive biases are seen during JJA in most stations. In general, the model overestimates CO from the middle to the upper troposphere throughout the year. Significant underestimation of CO is seen in Beijing below 600 hPa, a common result in other studies which strongly suggests an underestimation of anthropogenic emissions in China. The phase and amplitude of the seasonal cycles of CO at 800 and 500 hPa in NMMB-MONARCH and MOPITT are quite similar.

Overestimations of CO are mainly located over western-central Africa, western South America, Indonesia and the surrounding Pacific and Indian oceans during the dry season. At 800 hPa, a significant negative bias is observed at northern latitudes during winter. These results are most likely related to errors in anthropogenic and biomass burning emission inventories, where the magnitude and the location of the emission are not correctly represented.

Nitrogen oxide abundances are well simulated in almost all locations. Looking at the annual time series of NO₂ in Europe, the model captures the higher peaks during winter, although a positive bias is observed during summer. Nitrogen compounds are more sensitive to errors in emissions than other pollutants. We note that the emission inventory neglects seasonal variations for land-based anthropogenic emissions, and therefore we do not account for the potential reduction of NO_x emissions during summer. Over Asia, there is a negative bias of NO_x from March to August, probably due to underestimated emissions in this area. Vertical profiles of NO_x are really well captured by the model, although there is some underestimation in the upper troposphere, possibly due to the lack of lightning NO_x emissions. Vertical profiles of PAN and HNO₃ were also compared with observations. Some agreement is seen in these vertical profiles, although the model has a tendency to overestimate. HNO₃ wet deposition fluxes tend to be underestimated, and are better captured in the US compared to Europe and Asia.

The comparison with observed NO₂ VTC from SCIAMACHY shows that the model reproduces the seasonality and the spatial variability reasonably well, capturing higher NO₂ over the most polluted regions. However, the results show a tendency to underestimate NO₂ VTC in megacities, especially during DJF and SON, possibly due to a negative bias in the NO_x emissions. The biomass burning cycle is well captured by the model with higher NO₂ VTC in central Africa during DJF and in South America during JJA.

The ozone burden (348 Tg O₃) is in good agreement with other estimates from state-of-the-art global atmospheric chemistry models. The ozone burden in the southern extratropics is higher in our model, suggesting that higher CO concentrations in the SH could lead to excessive production of ozone in this area. It seems unlikely that the positive ozone biases are caused by too much STE. STE (384 Tg O₃) is consistent with other evaluation studies. In addition, STE has stronger effects in the upper troposphere. Therefore, biases should increase with height, which is not the case in our simulations.

The surface O₃ results show a reasonable agreement with the observations, with significant positive biases (~15 ppb) from May to October in the regions of the US and Japan. Surface O₃ concentrations are very sensitive to the emissions; consequently, the variability of ozone concentrations can be enhanced by improving the spatio-temporal distribution of the ozone precursor emissions.

The model captures the spatial and seasonal variation of background tropospheric O₃ profiles with a positive bias of ~5–20 ppb throughout the troposphere in most of the regions. The positive bias may be due to the significant overestimation of CO, especially in the free troposphere, potential biases in stratospheric O₃ or the lack of halogen and aerosol chemistry.

In summary, the NMMB-MONARCH provides a good overall simulation of the main species involved in tropospheric chemistry, although with some caveats that we have highlighted here. Future versions of the model will address problems identified in this study and will include the effect of aerosols in the system.
