Sustained Visual Attention is More Than Seeing—

The Dynamics of Gaze During Manual Actions
Abstract

Sustained visual attention is a well-studied cognitive capacity that is relevant to many developmental outcomes. The development of visual attention is often construed as an increased capacity to exert top-down internal control. We demonstrate that sustained visual attention, measured in terms of momentary eye gaze, emerges from and is tightly tied to sensory-motor coordination. Specifically, we examined whether and how changes in manual behavior alter toddlers’ eye gaze during toy play. We manipulated manual behavior by giving one group of children heavy toys that were hard to pick up, while giving another group of children perceptually identical toys that were lighter, easy to pick up and hold. We found a tight temporal coupling of visual attention with the duration of manual activities on the objects, a relation that cannot be explained by interest alone. In the heavy-object condition, toddlers looked at objects as much as did toddlers in the light-object condition, but did so through many brief glances, whereas looks to the same object were longer and sustained in the light-object condition. We explain the results based on the mechanism of hand-eye coordination and discuss its implications for the development of visual attention.

SUSTAINED VISUAL ATTENTION IS MORE THAN SEEING

Introduction

The visual world presents a flux of concurrent streams of sensory stimulation. Making sense of all this information requires selecting and sustaining attention on just some of it. Not surprisingly, infants and children’s ability to select and sustain attention on a target is predictive of learning in many domains (Fisher, Godwin, & Seltman, 2014; Kannass & Oakes, 2008; Ruff & Lawson, 1990; Yu & Smith, 2014). In the adult literature, visual attention is often studied as a visual process influenced from below by visual properties and from above or top-down by conceptual knowledge (Buschman & Miller, 2007; Egeth & Yantis, 1997; Posner, 1980). However, looking, or directing gaze to a target, is also an action that is tightly coordinated to other actions (E. J. Gibson, 1963; J. J. Gibson, 2015). Many developmentalists have argued that manual actions provide a context for sustaining—and learning to sustain—visual attention on objects (Needham, Barrett, & Peterman, 2002; Ruff, 1989; Yu & Smith, 2012, 2016b). Considerable evidence indicates that manual actions select information for attention and that manual actions are also associated with more enduring attention to an object (Hayhoe & Ballard, 2005; Yu, Smith, Shen, Pereira, & Smith, 2009). The central question for this paper is the mechanism through which manual actions provide the context for the development of sustained attention.

The starting point for the present study and the tested hypotheses is the seminal work of Ruff (1986; see also Ruff & Lawson, 1990). Her program of research defined sustained attention in terms of not just continuous visual attention to the object, but also included the toddler’s holding of the attended object. Sustained attention, defined in these terms of hands and eyes measures, has been shown to increase incrementally from toddlerhood through the preschool period and to predict future attention, self-regulation, and vocabulary development (Kannass &
Oakes, 2008; Lawson & Ruff, 2004; Razza, Martin, & Brooks-Gunn, 2010). More recent research using head-mounted eye trackers has confirmed the link between toddlers’ hand actions and gaze (Pereira, Smith, & Yu, 2014; Yu & Smith, 2014, 2016a). Toddlers’ visual attention to an object is more enduring, with positive consequences of a better memory for the object and associated name, when the visually attended object was also in contact with the hands (Pereira et al., 2014). Other studies indicate a tight temporal relation between hands and eyes: when engaged in active play, toddlers’ hands and eyes are dynamically coupled and move nearly simultaneously to the same object (Yu & Smith, 2013, 2017). This fact suggests the hypothesis tested in this paper: sustained gaze on an object may emerge early in development as a multimodal event and may be maintained by the joint sensory-motor inputs provided by eyes and hands. The hypothesis is not that hands temporally lead eyes to an object (as eyes generally but not always lead hands to the object (Pelz, Hayhoe, & Loeber, 2001), but rather that sustained hand actions directly sustain gaze.

Although sustained hand actions could lead to sustained gaze to the object through top-down conceptual effects or goals, the present hypothesis is that the effects of hand actions on gaze arise within the sensory-motor system itself through the real-time dynamic coordination of eye and hand movements. Although one can look at an object without touching it, making manual contact with an object typically requires looking to the object that is to be touched and continued manual engagement with an object might be expected at the sensory-motor level and entrain sustained looking. If gaze is tightly coordinated with goal-directed hand actions in this way for toddlers, then toddlers’ looking and acting on objects should be tightly aligned in time, such that altering the temporal structure of one should lead to corresponding changes of the other. This sensory-motor hypothesis fits evidence from studies of visual attention in human
adults and primates, which show direct effects of bodily actions on both gaze and the internal processes that underlie visual attention (Thura, Boussaoud, & Meunier, 2008). For example, eye movements (Grosbras, Laird, & Paus, 2005), head movements (Colby & Goldberg, 1999), and hand movements (Thura, Hadj-Bouziane, Meunier, & Boussaoud, 2008) bias visual attention in the direction of the movement.

The alternative hypothesis is that the association between handling objects and sustained attention in toddlers derives not from direct sensory-motor coupling, but from top-down motivation and conceptual factors. For example, an object that is interesting to look at is likely to also be interesting to touch and hold. If this is the case, the overall duration of interest to an object—as measured by gaze and by hand contact—may be expected to be correlated, but there is no strong prediction of direct dynamic coordination in time, that gaze and hands should move to and away from the object together in time. More specifically, by the sensory-motor hypothesis, if we alter the dynamics of hand contact to the objects, we should alter gaze dynamics as well. By the alternative hypothesis that hands and eye engagement are driven separately by top-down goals, then altering the dynamics of manual engagement need not alter the dynamics of gaze.

We tested these predictions by creating two identical sets of toys—designed and shown through pilot testing—to have properties that encourage manual exploration through a variety of hand actions. For both groups of children, the objects had holes and moveable parts that invited manual actions. For one group of children, the objects were light and easy to hold while being acted on. These toys should elicit long-lasting bouts of manual contact. For the other group of children, the same objects had weights put in them so that they were heavy and hard to hold. For these objects, we expected hand actions to emerge predominantly as a series of touches and
pokes as the heavy objects sat on the table. Figure 1 illustrates the main hypothesis and the alternative possibility. Figure 1A shows a stream of hand events in time, with each rectangle representing unbroken hand contact with an object. In the light-object condition, because toddlers can hold the object while manually exploring it, the expectation is that the duration of hand contact will be relatively long. In the heavy-object condition, because toddlers are expected to have difficulty holding the objects, the expectation is that hand contact with objects will occur in a series of brief touches, pokes and handling. Given these two different expected hand activities, the key prediction concerns the dynamics of gaze. If looking and acting on objects are tightly aligned temporally, then altering the temporal structure of hand contact should lead to corresponding changes in the temporal structure of gaze, such that continuous hand contact should support continuous eye contact and bursts of intermittent hand contact with a single object should support bursts of intermittent eye contact to that object—the temporal alignment hypothesis. Thus, as illustrated in Figure 1B, unbroken look durations should be longer in the light-object condition than in the heavy-object condition. The alternative possibility of shared top-down goals that independently affect eye and hand actions, what we will call the “interest” hypothesis, is illustrated in Figure 1C. When children are manually engaged with a single object, whether that engagement consists of continuous hand contact or bursts of hand activity to the same object, gaze will stay focused on the object of interest.

Methods

Participants

The final sample consisted of thirty-one parent–toddler (mean age = 21 months, range = 18-25) dyads. Roughly half (16) were assigned to play with light-weight toys, while the other half (15) played with heavy-weight toys. Data from one child who completed the study was not
included because of equipment failure. Children were recruited from a population of working and middle-class families in a Midwestern town. All parents provided informed consent. The sample size was adequate due to the high-density nature of the data—all participants wore head-mounted eye tracker that sampled at 30 Hz and on average contributed 11368 frames of data—and based on prior work using similar data collection method (Yu & Smith, 2013, 2016a).

**Stimuli**

Figure 2A shows the two sets of six novel toys that were developed from extensive pilot work to be engaging for manual play with moveable elements, openings, and possible actions. They were made of hardened clay, painted in red, blue or green, and were roughly the same size (9.5 x 6.5 x 5cm). The two sets were identical in terms of shape, size and color, with the only difference being their weight. The heavy toys (constructed by putting weights inside) averaged 639g, seven times heavier than the average weight of the toys in the light set, which was 91g.

**Context**

Because toddlers do not play with toys as consistently or happily when not with their parents, toy play was with one parent. As shown in Figure 2B, parent and child sat across a small table (61cm x 91cm x 64cm). The child sat in a small chair and the parent sat cross-legged on a pillow. Infants (and parents) wore head-mounted eye trackers with a sampling rate of 30 Hz (positive science, LLC; also see Franchak, Kretch, Soska, & Adolph, 2011). The eye tracker consisted of a scene camera that captured the egocentric view of the participant, and an infrared camera that was mounted on the head, pointed to the right eye of the participant, and recorded the eye-in-head position (x and y) in the captured scene. Another high-resolution camera (recording rate 30 Hz) was mounted above the table and provided a bird’s-eye view that was independent of participants’ movements.
Procedures

To place the eye tracker on the child’s head, one experimenter attracted the child’s attention with an interesting toy, while another experimenter put the eye-tracking gear low on the child’s forehead. To calibrate the eye tracker, the experimenter directed the child’s eyes toward an interesting toy, which was repeated 15 times while the toy was placed at various locations on the table. Parents were told that the goal of the experiment is to study how parents and their toddlers naturally interact during toy play and were instructed to play with their toddlers as naturally as possible. The free-play session lasted for a total of 6 minutes and was composed of four trials (each lasted 1.5 minutes). The six novel toys were grouped into two sets (A and B). Each set had three different colored objects (red, blue and green). The sets were interleaved, and the order was counterbalanced across dyads (ABAB or BABA). At the end of each trial, the experimenter signaled the parent with a clicking sound, and quickly replaced the old set of toys with a new set.

Coding

The eye-tracker sampled at 30 frames per second during the 6 minutes play session, yielding a theoretical 10800 frames of data. There was no significant difference in the number of recorded frames between the two experimental conditions ($t(30) = .51, p = .61$), and the total, final sample included a corpus of 352417 frames of data. Three regions-of-interest (ROI) were defined for the gaze data: the green, blue and red object. These ROIs were coded manually by naïve coders who annotated frame-by-frame when the participant fixated at any of the three ROIs. Another coder independently coded 29% of the frames with 86% agreement between coders (Cohen’s kappa = 0.81). Hand contact was coded based on the frame-by-frame images captured by the eye-tracker. Three ROIs were defined as when the participant was in manual
contact with any of the three objects: the green, blue and red object. The coders also consulted
the third-person view camera in the case of uncertainty (e.g., the physical contact between a hand
and an object could not be reliably determined). Another coder independently coded 29% of the
frames with 98% agreement between coders (Cohen’s kappa = 0.96). These resulted in two
temporally synced streams of data—eye gaze and manual action. Figure 3C provides sample data
from one participant, top row: child’s eye gaze on the objects, middle row: child’s left hand in
contact with the objects, bottom row: child’s right hand in contact with the objects. In all
following analyses, data from right and left hands were coded individually and then combined as
manual contact defined as either or both hands. The duration of each event or bout was defined
as a continuous hand contact or gaze on an object and was calculated by summing all frames
within the event.

All of the analyses reported in the results section focused on children’s behavior only, as
it is directly related to our hypotheses. However, because social partners interact during play, and
children’s behavior could be affected by parents’ behavior, not the specific manipulation of the
toys, we also coded and analyzed parents’ gaze and hand contact data. We found no significant
difference in parents’ behavior between the two conditions. These results are included in the
supplemental material.

Results

We first report on infants’ hand contact with the objects and then turn to the main
questions—whether the dynamics of gaze are aligned with the dynamics of hand actions.

The dynamics of manual actions

As shown in Table 1, the hands of children in the heavy-object condition and the light-
object conditions contacted the objects for a comparable amount of total time, \( t(29) = .36, p \)
SUSTAINED VISUAL ATTENTION IS MORE THAN SEEING

= .7, and there was no significant difference in the proportion of total play time that children in the light-object and the heavy-object condition were in hand contact with the objects, $t (29) = .24, p = .8$. Further, hand contact bouts from both conditions were distributed across the three toys. In terms of total amount of hand contact, then, the toys in both the heavy-object and light-object conditions were comparably engaging to the children. However, as expected, the dynamics of hand contact differed across the two conditions. Figure 3A (left) shows the frequency (count per min) distribution of the durations of hand contact in both conditions. As with most natural behaviors, these distributions were not normal but skewed such that most hand contacts were very brief, but some were quite long. Statistical analyses assuming normal distributions of data (e.g., t-test) are not appropriate for these extremely skewed distributions (Gibbons & Chakraborti, 2011) as there is no central tendency. Accordingly, our analysis plan for the durations of hand contact (and subsequently for the durations of looking) used two approaches. The first is an event-level analysis in which we compared the entire frequency distribution of all object contact durations from the two conditions collapsed across children. As can be seen in Figure 3A (left), a Mann-Whitney-Wilcoxon test revealed that the distributions of durations in the two conditions were significantly different ($U = 1800000, p < .001$): as expected, the duration of manual actions were briefer in the heavy-object condition ($Mdn = 0.8s; M = 2.43s$) than those in the light-object condition ($Mdn = 1.16s; M = 3.29s$).

The second analysis was an individual-level analysis in which we constructed two scores for each child: the proportion of all looks that fell at two duration categories—very brief durations (the head of the right-skewed distributions; less than 1 second) and substantially longer durations (the tail of the distribution; more than 3 seconds, the threshold for sustained visual attention used by Ruff & Lawson, 1990 and by Yu & Smith, 2016). Although we leave out the
middle durations, these two measures (accounting for 78% of data) and normalized by subject for the total number of acts are dependent. Therefore, we also report a secondary analysis based on the total number of events rather than proportion. A linear mixed-effect regression model was conducted using the lme4 package in R (Version 3.0.1; Bates, Mächler, Bolker, & Walker, 2014); p values for regression coefficients were obtained using the car package (Fox & Weinberg, 2011). Condition (heavy-object vs. light-object) and event type (brief vs. sustained) were submitted as fixed effects and subject was submitted as a random effect. As shown in Figure 3A (right), there was a significant interaction between condition and event type (b = -0.05, SE = 0.02, p = .037). The heavy-object condition had a higher proportion of brief looking events than the light-object condition (52% vs. 46%), but the light-object condition had a higher proportion of sustained looking events than the heavy-object condition (30% vs. 25%). The same analysis when conducted on the total number of hand contacts in each duration category yielded the same significant interaction between condition and event type (b = -11.69, SE = 5.63, p = .037). In sum, children in the light-object condition picked up and held objects, resulting in fewer but longer manual contact events; children in the heavy-object condition generated more but briefer manual contacts with the objects.

Figure 4 top panel shows our expectation of how touches would be distributed in the heavy-object condition—repeated brief touches and pokes to the same object. However, it is also possible that the heaviness of the objects could disrupt play more dramatically such that children in the heavy-object condition often switched between objects—e.g., a touch to the blue object followed by a touch to the red object. The evidence supports our expected pattern. There was no significant difference in the frequency of switches between different objects in the heavy-object condition (M = 5.75; SD = 2.27) and the light-object condition (M = 5.12; SD = 2.4), t(29)
= .74, \( p = .46 \); However, the frequency of repeated hand contact to same object was significantly higher in the heavy-object condition (\( M = 16.01; SD = 6.67 \)) than the light-object condition (\( M = 10.51; SD = 3.76 \)), \( t (29) = 2.85, p = .008, d = 1.01 \), as hand activity in the heavy-object condition consisted of a series of touches to the same object. Thus, toddlers in the heavy-object condition often touched the same object repeatedly in short bursts, whereas toddlers in the light-object condition often maintained hand contact with the explored object for a long time.

These results set the stage for the main question: given that hand dynamics differ between the two conditions, do eye dynamics differ as well? Is gaze to objects in shorter bursts when the objects are heavy, but sustained when the objects are lighter and thus in longer contact with hands?

**The dynamics of gaze**

As shown in Table 1, children in the light-object condition and the heavy-object condition looked at the objects for the same total amount of time, \( t (29) = .24, p = .8 \), as well as in the proportion of play time spent looking to the objects, \( t (29) = .52, p = .6 \). Further, looking events from both conditions were distributed across the three toys. As predicted, the dynamics of gaze differed between the two conditions. Figure 3B (left) shows the frequency (count per min) distribution of the durations of all individual looking events (across all children) for each condition. A Mann-Whitney-Wilcoxon test revealed a significant difference between the distributions (\( U = 1900000, p < .001 \)) supporting the hypothesis: looking events was briefer in the heavy-object condition (\( Mdn = 1.03s; M = 1.9s \)) than in the light-object condition (\( Mdn = 1.26s; M = 2.3s \)). For the individual-level analysis, we constructed two scores for each child: the proportion of all looks that fell at two duration categories—very brief durations (the head of the right-skewed distributions; less than 1 second) and substantially longer durations (the tail of the...
distribution; more than 3 seconds, a common threshold for sustained attention, Ruff & Lawson, 1990; Yu & Smith, 2016). A Linear mixed-effect regression model was conducted, in which condition (heavy-object vs. light-object) and event type (brief vs. sustained) were submitted as fixed effects and subject was submitted as a random effect. As shown in Figure 3B (right), there was a significant interaction between condition and event type (b = -0.07, SE = 0.02, p < .001). The heavy-object condition had a higher proportion of brief looking events than the light-object condition (48% vs. 41%), but the light-object condition had a higher proportion of sustained looking events than the heavy condition (25% vs. 20%). The same analysis when conducted on the total number of looking events in each duration category yielded the same significant interaction (b = 10.6, SE = 4.34, p = .02).

In sum, the results of the looking patterns mirror the results of the hand contact activity: children in the heavy-object condition produced more rapid but frequent hand contact events, as well as more rapid but frequent looking events, compared to children in the light-object condition. Sustained hand contact is thus associated with sustained gaze. In other words, by the definitions of sustained attention (continuous gaze to an object longer than 3 sec) used in previous research (Ruff & Lawson, 1990; Yu & Smith, 2016b), children in the light-object condition showed more sustained attention than children in the heavy-object condition.

**The dynamics of gaze during manual action**

By hypothesis, the common dynamics of hand and eye in the two conditions reflects a direct effect: hand contact sustains eye contact because the two actions are temporally coordinated within the sensory-motor system. Thus, long durations of hand contact in the light-object condition should *coincide* with long durations of gaze to the same object, and short duration of hand contact in the heavy-object condition should *coincide* with short durations of
gaze to the same object, a key component of the predictions not addressed in the above analyses. To test this prediction, we measured the durations of joint hand and eye directed to the same object. Figure 3C (left) shows the frequency distributions of looking events during hand contact and Mann-Whitney-Wilcoxon indicated that the distributions were significantly different between the two conditions (U = 1400000, p < .001): joint eye-hand events were briefer in the heavy-object condition (Mdn = 0.5s; M = 1s) than those in the light-object condition (Mdn = 0.7s; M = 1.3s). For each child, we further calculated the proportion of those joint eye-hand events that were less than a second and those that were more than 3 seconds. A Linear mixed-effect regression model was conducted, in which condition (heavy-object vs. light-object) and event type (brief vs. sustained) were submitted as fixed effects and subject was submitted as a random effect. As shown in Figure 3C (right), there was a significant interaction between condition and event type (b = -0.06, SE = 0.01, p < .001): the heavy-object condition had a higher proportion of brief joint eye-hand events than the light-object condition (67% vs. 59%), but the light-object condition had a higher proportion of sustained joint eye-hand events than the heavy-object condition (12% vs. 8%). In sum, the heavy-object condition is characterized by shorter joint hand-eye events in which toddlers’ hands and gaze were on the object at the same time and the light-object condition is characterized by longer joint hand-eye events in which toddlers’ hands and gaze were on the same object.

**General Discussion**

The main finding is this: altering the temporal dynamics of manual action led to corresponding changes in the temporal dynamics of visual attention. Past research (Ruff, 1986, 1989; Ruff & Lawson, 1990) indicated an association between toddlers’ holding of an object and sustained visual attention, with holding interpreted as a sign of effortful focused attention. In the
SUSTAINED VISUAL ATTENTION IS MORE THAN SEEING

present study, children who played with light easy-to-hold toys showed both continuous hand contact and more sustained visual attention, behavior fitting the prior characterization of focused attention. However, children who played with just-as-interesting but heavy toys manually engaged with those toys in briefer bursts of hand activity and, because gaze was coupled to their hand actions, also showed less sustained attention. These facts suggest that continuous hand contact may not be a mere sign of focused attention, but instead may play an instrumental role in sustaining the duration of gaze to an object. These results also suggest that sustained attention is more likely with objects that support prolonged manual contact versus those that do not. If object play provides a context not just for measuring sustained attention but also for its development (Wass, Porayska-Pomsta, & Johnson, 2011; Yu & Smith, 2016b), then these objects that support longer manual contact may be a key training ground for the development of sustained attention.

The findings also raise a new mechanistic route through which toddlers may control their visual attention through their own actions. Visual attention is typically thought of as determined exogenously by the attention-getting properties of the visual stimulus or endogenously through top-down control (Colombo, 2001; Emberson, 2017; Richards & Casey, 1992; Ruff & Capozzoli, 2003). But neither of these routes seem to explain the present results. Children in the heavy-object condition, who played with the objects just as much as children in the light-object condition, could have sustained their gaze on the acted-on object while their fingers and hands poked and jabbed the object during their manual explorations, but they did not. Instead, the dynamics of hands and eyes were aligned in more rapid bursts to the objects while the aligned dynamics of the hands and eyes of the children in the light-object condition included more enduring hand contact and gaze. There is no easy explanation of this finding through traditional
ideas of exogenous or top-down control as toddlers visually attended to and manually engaged with the objects for comparable total durations across the play session. Instead, the present findings were predicted from and implicate a multi-modal pathway in which the co-activation of a second sensory-motor system directed to the same object—hand contact—entrains gaze so that longer hand contact sustains longer looks and shorter hand contact is associated with shorter looks to the object.

Looking—directing and maintaining gaze to an object—is a motor act. A large body of literature have documented the role of engaged manual and visual exploration of objects in supporting stabilized and aligned heads, eyes, and posture (e.g., Bertenthal & von Hofsten, 1998; Saavedra, Woollacott, & van Donkelaar, 2010; Soska, Galeon, & Adolph, 2012) with positive consequences for visual learning about objects (Baumgartner & Oakes, 2013; Soska, Adolph, & Johnson, 2010; Woods & Wilcox, 2013), visual attention (Needham et al., 2002) and joint attention (de Barbaro, Johnson, Forster, & Deák, 2016; Yu & Smith, 2014). Other evidence shows that holding objects stabilizes posture and head movements in early sitters and walkers (Claxton, Melzer, Ryu, & Haddad, 2012; Claxton, Strasser, Leung, Ryu, & O’Brien, 2014). We propose that through perhaps similar intersensory processes, holding objects stabilizes the motor act of gaze to an object. This hypothesis of a direct multisensory pathway in sustaining attention fits with evidence from adults showing considerable manual-visual interactions in behavior and neural processing (Abrams, Davoli, Du, Knapp, & Paull, 2008; Macaluso & Driver, 2001; Macaluso, Frith, & Driver, 2000; Park & Reed, 2015; Taylor-Clarke, Kennett, & Haggard, 2004) and developmental findings and theories on the especially important role of intersensory interactions in early developmental process (Bahrick & Lickliter, 2000; Brenna et al., 2015; Lewkowicz & Lickliter, 1994).
Because sustained attention in late infancy is predictive of future development and because deficits in sustained attention are markers for later diagnoses of attentional disorders (Barkley, 1997; Jones, Rothbart, & Posner, 2003), the current findings have direct consequences for understanding the developmental origins of individual differences in sustained attention (Iverson, 2010). There are growing suggestions that the development of sustained visual attention during infancy has a strong experiential component and individual differences may arise from experiences that depend on sensory-motor co-ordinations including those between hands and eyes (Wass et al., 2011; Yu & Smith, 2014). This idea is consistent with findings showing that sensory-motor dis-coordinations are often the earliest signs of atypical development and predictive of long-term outcomes across many domains (D’Souza, Cowie, Karmiloff-Smith, & Bremner, 2017; Provost, Lopez, & Heimerl, 2007). It is also consistent with correlational and experimental studies linking object manipulation to object name learning, object memory, and object attention (James, Jones, Smith, & Swain, 2014; Needham et al., 2002). The present findings suggest the potential value of objects and tasks that invite and sustain manual contact as a possible malleable factor in supporting sustained attention.

In conclusion, the present findings illustrate how visual attention develops in a larger network of behaviors that involve much more than vision itself (Byrge, Sporns, & Smith, 2014). The tight coordination of hands and eyes in toddlers has direct real-time effects on sustained visual attention and we propose that these may support the development of visual attentional skills. The larger idea that development in one domain depends on and supports developments in other domains—even ones seemingly far—is consistent with developmental systems views (Gottlieb, 2007; Oyama, Griffiths, & Gray, 2003; Thelen & Smith, 1994) and the role of behavior in the development of functional and structural brain networks (Byrge et al., 2014;
Herholz & Zatorre, 2012). Visual attention in real time emerges from at least two sensory modalities—haptic and visual—and two motor actions—manipulation and gaze—that are dynamically coordinated during moment-by-moment engagement with objects. Unbroken manual contact with an object provides the context for unbroken gaze on the object. The real-time effects of sustained holding and looking over developmental time may build the circuitry that supports internally driven sustained visual attention to a target. This is a key hypothesis for future research.

*Note.* Total time is in seconds. Standard Deviations are in brackets. Prop. = proportion. Obj = object.
SUSTAINED VISUAL ATTENTION IS MORE THAN SEEING

A. Hand contact expectation

![Illustration of hand contact expectation]

B. Visual attention: The temporal alignment hypothesis

![Illustration of visual attention temporal alignment]

C. Visual attention: The interest hypothesis

![Illustration of visual attention interest]

Figure 1. Illustrations of the hypotheses. The colored rectangles represent a series of hand and eye contact with an object; the duration of the contact is indicated by the length of the rectangle. The different color represents different objects: blue → the blue object, red → the red object, and green → the green object. Row A represents the expectation for hand contact: children in the heavy-object condition would have more short but frequent hand contact than those in the light-object condition because of the weight of the objects. Row B represents the temporal alignment hypothesis for visual attention: if manual actions and gaze are tightly aligned in time, then altering the temporal structure of manual actions would lead to corresponding changes in the temporal structure of gaze. Row C represents the interest hypothesis for visual attention: that looking behavior is driven by interest, then gaze durations should not differ as long as the hand actions (continuous contact or intermittent contact) remain on the same object.
A. The six novel toys

![Image of six toys]

B. The experimental setup

![Images of child's and parent's egocentric views with eye trackers and hands in contact]

C. Sample data streams

![Sample data stream chart]

Figure 2. Illustrations of the experimental method. A) The six novel toys used in the study. The heavy and light set of toys were perceptually identical except for their weight. B) The experimental setup. Left and right: eye tracker images from the child’s and parent’s egocentric view. Middle: child and parent both wore head-mounted eye trackers. C) Sample data from one participant. Three streams of time-locked sensory data—eye gaze (top stream), left-hand hand contact (middle stream) and right-hand hand contact (bottom stream)—were shown from the onset of the experiment to 35s later. Colors represent the three regions of interest (blue → the blue object, red → the red object, and green → the green object).
Figure 3. Left panels: frequency of events that last for different durations. Right panels: proportion of brief (less than 1 second) and sustained (more than 3 seconds) events in the heavy-object and light-object conditions. Error bars represent standard error. Row A: hand contact events. Row B: looking events. Row C: joint eye-hand events.
Figure 4. Two possible hand contact patterns in the heavy-object condition consistent with briefer durations of hand contact: Top – a series of contacts with one object before switching to another; Bottom – a series of brief contacts to different objects. The pattern in the top row was supported by the empirical data.
Supplemental material: Analyses of parents’ behavior

Parents’ gaze and hand contact data were coded in the same way as those from the children. In the following sections, we report the analyses of parents’ hand contact, visual attention and hand-eye coordination patterns. In all of these analyses, we did not find evidence suggesting a significant difference in parents’ behaviors between the heavy-object condition and the light-object condition. Therefore, the different patterns in children’s behaviors between the two conditions were not likely due to differences in their parents’ behaviors, but were rather driven by the experimental manipulation on the weights of objects.

Hand contact

A Linear mixed-effect regression model was conducted using the lme4 package in R (Version 3.0.1; Bates, Mächler, Bolker, & Walker, 2014); p values for regression coefficients were obtained using the car package (Fox & Weinberg, 2011). We calculated the proportion of all hand contacts that fell at two duration categories—very brief durations (the head of the right-skewed distributions; less than 1 second) and substantially longer durations (the tail of the distribution; more than 3 seconds). Condition (heavy objects vs. light objects) and event type (brief vs. sustained) were submitted as fixed effects and subject was submitted as a random effect. There was no significant interaction between condition and event type (b = -.06, SE = 0.06, p = .27). The heavy-object condition and the light-object condition had comparable numbers of brief hand contact events (50% vs. 48%), as well as more sustained hand contact events (24% vs. 27%).

Visual attention

A Linear mixed-effect regression model was conducted. Condition (heavy objects vs. light objects) and event type (brief vs. sustained) were submitted as fixed effects and subject was
submitted as a random effect. We calculated the proportion of all looks that fell at two duration categories—very brief durations (the head of the right-skewed distributions; less than 1 second) and substantially longer durations (the tail of the distribution; more than 3 seconds). There was no significant interaction between condition and event type ($b = .01, SE = 0.03, p = .65$). The heavy-object condition and the light-object condition had comparable numbers of brief looking events (74% vs. 75%), as well as more sustained looking events (5% vs. 4%).

**Visual attention during hand contact**

A Linear mixed-effect regression model was conducted. Condition (heavy objects vs. light objects) and event type (brief vs. sustained) were submitted as fixed effects and subject was submitted as a random effect. We calculated the proportion of all looking events that fell at two duration categories—very brief durations (the head of the right-skewed distributions; less than 1 second) and substantially longer durations (the tail of the distribution; more than 3 seconds). There was no significant interaction between condition and event type ($b = .002, SE = 0.02, p = .93$). The heavy-object condition and the light-object condition had comparable proportions of brief looking events (79% vs. 79%), as well as more sustained looking events (2% vs. 2%).
