Keywords: cytochrome, sulfur metabolism, electron transfer, magnetic circular dichroism (MCD), electrochemistry, protein film electrochemistry (PFE), biogeochemical sulfur cycle, tetrathionate reductase, thiosulfate oxidase, thiosulfate dehydrogenase.

ABSTRACT

Thiosulfate dehydrogenases (TsdA) are bidirectional bacterial di-heme enzymes that catalyze the interconversion of tetrathionate and thiosulfate at measurable rates in both directions. In contrast to our knowledge of TsdA activities, information on the redox properties in the absence of substrates is rather scant. To address this deficit, we combined magnetic circular dichroism (MCD) spectroscopy and protein film electrochemistry (PFE) in a study to resolve heme ligation and redox chemistry in two representative TsdAs. We examined the TsdAs from Campylobacter jejuni, a micro-aerobe human pathogen, and from the purple sulfur bacterium Allochromatium vinosum. In these organisms, the enzyme functions as a tetrathionate reductase and a thiosulfate oxidase respectively. The active site Heme 1 in both enzymes has His/Cys ligation in the ferric and ferrous states and the midpoint potentials (Em) of the corresponding redox transformations are similar, −185 mV versus standard hydrogen electrode (SHE). However, fundamental differences are observed in the properties of the second, electron transferring, Heme 2. In C. jejuni TsdA Heme 2 has His/Met ligation and an Em of +172 mV. In A. vinosum TsdA, Heme 2 reduction triggers a switch from His/Lys ligation (Em, −129 mV) to His/Met (Em, +266 mV) but the rates of interconversion are such that His/Lys ligation would be retained during turnover. In summary, our findings have unambiguously assigned Em values to defined axial ligand sets in TsdAs, specified the rates of Heme 2 ligand exchange in the A. vinosum enzyme, and provided information relevant to describing their catalytic mechanism(s).

Redox active molecules within the biogeochemical sulfur-cycle can serve as sources of, or sinks for, the electrons transferred in energy conserving pathways. An example is the oxidative coupling of two thiosulfate molecules to form tetrathionate:

\[ 2 \text{S}_2\text{O}_3^{2−} ⇌ \text{O}_3\text{S-S-SO}_3^{2−} + 2e^- \]  
\( (E_m = +198 \text{ mV vs SHE}) \)

This oxidation is well-established in many obligitory chemolithoautotrophic sulfur-oxidizing bacteria and also serves as a source of electrons for
Some purple (non)-sulfur bacteria (2). The reverse reaction, tetrathionate reduction, can terminate anaerobic respiratory electron transfer chains in a process thought to confer growth advantage in the micro-aerobic environment of intestinal mucosa (3). Both thiosulfate oxidation and tetrathionate reduction are catalyzed by the phylogenetically widespread family of periplasmic thiosulfate dehydrogenase (TsdA) enzymes (2).

Two of the best characterized di-heme TsdA enzymes are those from the purple sulfur bacterium *Allochromatium vinosum* (*Av*) and the micro-aerobe *Campylobacter jejuni* (*Cj*), the latter a commensal in the small intestine of birds and one of the main causes of bacterial food borne disease in humans. These enzymes have 41% sequence similarity (Fig. S1) and contain two c-type hemes. Nevertheless their cellular roles illustrate the contrasting activities required of TsdA: thiosulfate oxidation by *Av*TsdA provides electrons for photosynthesis while *Cj*TsdA allows use of tetrathionate as a terminal respiratory electron sink (3). However, spectrophotometric assays (4,5) of the purified enzymes reveal detectable catalysis in both directions (Fig. 1) showing that neither is restricted to performing the physiologically required redox transformation. For *Cj*TsdA the maximum rate of tetrathionate reduction is approximately twice that of thiosulfate oxidation. For *Av*TsdA the maximum rate of oxidative catalysis greatly exceeds that of reductive catalysis. For TsdA enzymes isolated to date from other organisms (4-7) the relative rates of these two activities also correlate with their metabolic role, organisms (4-7) the relative rates of these two activities also correlate with their metabolic role, however, the molecular basis of these differing behaviors remains unclear.

The crystal structure of as-isolated (di-Fe(III)) *Av*TsdA (4,6) shows the closest edge-to-edge approach of the two hemes to be 8.1 Å, consistent with rapid inter-heme electron transfer. The proximal and distal axial ligands, respectively, are His$^{99}$ and Cys$^{138}$ to Heme 1 and His$^{164}$ and Lys$^{208}$ to Heme 2 (Fig. 2). However, crystals exposed to reducing agent (dithionite ion), show Lys$^{208}$ is replaced by Met$^{209}$ as distal ligand to Heme 2 and this exchange is a proposed consequence of a two-electron reduction within the crystal (4). Several observations point towards Heme 1 having an intimate role in thiosulfate/tetrathionate interconversion. The catalytic activity of *Av*TsdA in both directions is abolished by site directed mutagenesis of Cys$^{96}$ (4). Two nearby and conserved residues, Arg$^{109}$ and Arg$^{119}$ (see Fig. S1 for comparison of TsdA sequences), are important for activity and proposed to play a role in substrate binding by analogy with the SoxAX cytchromes that catalyze formation of a disulfide bond between thiosulfate and a cysteine of SoxYZ (6). Furthermore, exposure of *Av*TsdA to substrates leads to covalent modifications of Cys$^{96}$, some of which carry an additional sulfur and may be relevant to catalysis (4,6).

The structural properties of *Av*TsdA provide a basis for predicting the heme ligands in *Cj*TsdA (5). Significantly Lys$^{208}$ is not conserved and the corresponding residue in *Cj*TsdA is the non-coordinating Asn$^{224}$ (see Fig. S1). However, the four remaining *Av*TsdA heme ligands, namely Cys$^{96}$, Met$^{209}$ and the two proximal histidines, are conserved in *Cj*TsdA (2). Thus, in all oxidation states of *Cj*TsdA the corresponding residues His$^{99}$/Cys$^{138}$ and His$^{164}$/Met$^{255}$ are implicated as the ligand sets to Heme 1 and 2, respectively (5). Replacing Cys$^{138}$ with either His or Met produced proteins, *Cj*TsdA C138H and *Cj*TsdA C138M respectively, that lack catalytic activity in both directions (5). The impact of possibly recreating at *Cj*TsdA Heme 2 the His/Lys ligation of *Av*TsdA, and potentially a redox linked ligand switch at that center, was tested by introducing lysine as residue 254 (5). The maximum rate of tetrathionate reduction by the resulting protein, *Cj*TsdA N254K, was comparable to that achieved by *Cj*TsdA but that of thiosulfate oxidation was approximately 10-fold slower (Fig. 1). The catalytic behavior of the *Cj* enzyme did not become more like that of *Av*TsdA following modification to the Heme 2 environment.

In contrast to our knowledge of TsdA activities, information on their redox properties in the absence of substrates is lacking. In a previous report we described spectroelectrochemical characterization of *Av*TsdA adsorbed on SnO$_2$ electrodes (8). Protein reduction was observed on poising the electrode at increasingly negative potentials, from +150 to −359 mV vs SHE. However, re-oxidation was slower to occur and incomplete even at +330 mV. The complex behavior, combined with the lack of structural information afforded by electronic absorption spectroscopy, prevented unambiguous assignment of redox properties to Heme 1 or 2. As a consequence we were motivated to use a combination of Magnetic Circular Dichroism
(MCD) and Protein Film Electrochemistry (PFE) to gain greater insight into the redox properties of TsdA enzymes. Here we present the corresponding studies of AvTsdA, CJTsdA and variants of the latter, namely CJTsdA N254K, CJTsdA C138H and CJTsdA C138M. \( E_m \) values for Fe(III) \( \pi \rightarrow (\pi) \) transitions of TsdA hemes are defined and the greater resolving power of MCD as compared to electronic absorbance spectroscopy allows, for the first time, their unambiguous assignment to sites of defined axial ligand sets. Furthermore, we provide insight into the rates of Heme 2 ligand exchange. The results address a significant gap in our knowledge of TsdA enzymes and contribute to wider discussions relating to the catalytic mechanism(s) operating in this enzyme family.

**Results**

**MCD characterization of Av and CJ TsdA enzymes.**

MCD probes the same electronic transitions as electronic absorption spectroscopy but offers significant advantages. Signed bands and substantial variations in intensity of the porphyrin \( \pi-\pi^* \) transitions in the UV-visible region identify, and quantify, spin and oxidation state of the iron. Furthermore, at longer wavelengths, MCD can locate ligand to metal charge transfer (CT) transitions that are diagnostic of the axial ligands to Fe(III) heme (9,10); a pair of bisignate bands (CT\(_1\) at 800 – 1300 nm and CT\(_2\) at 600 – 660 nm) for high-spin; a single positive band for each low-spin heme (CT\(_{LS}\) at 1000 – 2500 nm).

MCD spectra of the fully oxidized TsdA enzymes are presented in Fig. 3. CJTsdA displays two nIR CT\(_{LS}\) bands at 1215 nm and 1825 nm (Fig. 3B) with the latter having an associated vibrational sideband near 1600 nm (nIR MCD wavelengths for low-spin Fe(III) centers characterized in this work are collected in Table S1). The 1825 nm wavelength is diagnostic of His/Met ligated Fe(III) heme and accordingly is assigned to Heme 2. The 1215 nm band lies in the range of wavelengths reported for hemes coordinated by a nitrogen ligand distal to Cys\(^-\) (10-12) and is assigned to Heme 1 (the Cys\(^-\)/H\(_2\)O ligation found in P450 cytochromes results in an nIR CT band to shorter wavelength, 1050 – 1100 nm (11)). However, it should be noted that the nIR CT bands resulting from R-S-S\(^-\) (persulfide or sulfane) ligation may lie at similar wavelengths to those for cysteinate (13-15).

Between 300 and 800 nm, the MCD is dominated by a bisignate feature at 415 nm characteristic of low-spin Fe(III) heme and with a peak to trough intensity of \( 215 \text{ M}^{-1} \text{cm}^{-1} \text{ T}^{-1} \) (Fig. 3A). For His/Cys\(^-\) ligated Fe(III) hemes, such features have an anomalously low peak-to-trough intensity of \( 50 – 90 \text{ M}^{-1} \text{cm}^{-1} \text{ T}^{-1} \), compared to \( ~150 \text{ M}^{-1} \text{cm}^{-1} \text{ T}^{-1} \) typical for other ligand sets (16-25). The 415 nm intensity from CJTsdA is therefore entirely consistent with His/Cys\(^-\) ligation at Heme 1 and His/Met ligation at Heme 2. MCD thus confirms, for CJTsdA in solution, the heme ligands predicted from sequence alignments and electronic absorbance spectroscopy (5).

Interpretation of the MCD of oxidized AvTsdA (Fig. 3B) is more complex than for CJTsdA. A positive CT feature is observed at 1505 nm, a wavelength diagnostic of low-spin Fe(III) heme with two nitrogenous axial ligands and therefore indicative of His/His or His/Lys ligation (10). However, the intensity is significantly higher than observed for any His/His ligated Fe(III) heme but similarly high intensities have been reported for examples of His/Lys(or amine) coordination (26-28). The His/Lys coordination, observed at Heme 2 in the crystallographically determined structure of AvTsdA, is therefore also present in the oxidized enzyme in solution. The feature at \( ~1250 \text{ nm} \) is unusually pronounced and unlikely to arise entirely from the vibrational sideband to the 1505 nm band. The more likely explanation is that a CT band from Heme 1 also contributes to this feature. This is supported by the interpretation of the UV-visible MCD (discussed below) that necessitates the presence of an nIR CT band from Cys\(^-\)/His-ligated low-spin Heme 1.

The general intensities and band shapes of AvTsdA MCD in the 300 – 600 nm region (Fig. 3A) can be interpreted in the same manner as for the corresponding CJTsdA features shown in the same panel. Specifically, the spectrum indicates the presence of two low-spin Fe(III) hemes, one of which has a Cys\(^-\) ligand since the bisignate feature at 407 nm has a peak-to-trough intensity of approximately \( 230 \text{ M}^{-1} \text{cm}^{-1} \text{ T}^{-1} \). The negative component of this feature clearly resolves distinct contributions from the two differently ligated low-spin Fe(III) hemes while for CJTsdA the corresponding feature is a single broad lobe. The narrower features resolved for AvTsdA are again consistent with the presence of bis-nitrogenous ligation proposed for Heme 2 from the nIR MCD.
**MCD Characterization of semi- and fully-reduced AvTsdA.**

Fig. 4AB(red) shows the MCD of AvTsdA following incubation with 1.5 mM ascorbate (producing an effective potential of ~60 mV, see Materials and Methods). There is a loss of intensity, compared to the MCD of the oxidized enzyme (black dotted), in the 407 nm bisignate feature associated with low spin Fe(III) heme, together with the appearance of two features characteristic of low-spin Fe(II) heme, namely an asymmetric bisignate feature at 425 nm and a narrow bisignate band centered at 554 nm with a peak to trough intensity of ~275 M⁻¹ cm⁻¹ T⁻¹. The atypical MCD properties of Cys⁻ ligated hemes are such that, in the Fe(II) state, they give rise to broad and relatively weak visible region bands (17). The high intensity and narrow linewidth of the 554 nm feature suggests therefore that it could arise from reduction of Heme 2. This is confirmed by the nIR MCD (Fig. 4B) in which the intensity at 1505 nm due to His/Lys Fe(III) heme has diminished to ~13% of that observed for fully oxidized AvTsdA. Concomitant loss of the corresponding vibrational sideband at wavelengths between 1100 and 1400 nm means that there should now be negligible MCD intensity in this region from Heme 2. However, significant intensity persists at these wavelengths and, as suggested earlier, can be assigned as the CT band of His/Cys⁻ ligated Fe(III) Heme 1, which is unaffected by ascorbate. The peak wavelength, at 1240 nm, matches that of the corresponding feature for the oxidized Cj enzyme (Fig. 3B). A peak to trough intensity at 554 nm of ~275 M⁻¹ cm⁻¹ T⁻¹ for 87% reduction of Heme 2 implies a value of ~315 M⁻¹ cm⁻¹ T⁻¹ for full reduction. This is lower than typically observed for hemes with bis-nitrogenous coordination but falls in the range observed for His/Met ligation, implying that a ligand switch has occurred on reduction of Heme 2, as illustrated in Scheme 1A.

Following anaerobic incubation of AvTsdA with the stronger reducing dithionite (1.5 mM, effective potential = ~500 mV), the MCD in the wavelength range 300 – 600 nm (Fig. 4A, blue) showed no features associated with Fe(III) heme, demonstrating complete reduction of both hemes. The dominant low-spin Fe(II) bisignate feature at 554 nm has increased in intensity compared to the ascorbate reduced form. However, the increase is almost four times that anticipated for reduction of the residual (~13%) of Fe(III) His/Lys Heme 2 implying that reduced Heme 1 makes a significant contribution to this feature and one that is larger than expected for simple reduction of a His/Cys⁻ ligated heme. A similar observation was reported for the reduction of the active site His/Cys⁻ ligated heme in SoxAX and was attributed to protonation of Cys⁻ upon reduction (29). However, it should also be noted that a similar spectral response is anticipated if Cys⁶ is replaced by hydrogen sulfide as was observed in the crystal structure following dithionite reduction. A small positive band at 440 nm, characteristic of high spin Fe(II) heme and with an intensity (12 M⁻¹ cm⁻¹ T⁻¹) sufficient to account for 0.10 – 0.25 of a heme, is also consistent with the crystal structure that showed approximately 25% of Heme 1 in a five-coordinate state.

**MCD Characterization of semi- and fully-reduced CjTsdA.**

Incubation of CjTsdA with 1.5 mM ascorbate also produces a semi-reduced form of the enzyme (Fig. 4CD, red). The resultant changes in the MCD spectrum are broadly similar to those described for AvTsdA. However, with negligible positive intensity at 400 nm and a peak to trough intensity at 550 nm of 365 M⁻¹ cm⁻¹ T⁻¹ the extent of heme reduction by ascorbate is greater in Cj than AvTsdA. Indeed, in the nIR all intensity above 1500 nm is removed while that of the peak at 1210 – 1220 nm is unaffected. Therefore Heme 1 remains fully oxidized upon incubation of CjTsdA with ascorbate and Heme 2 is fully reduced. This indicates a higher $E_m$ for Heme 2 in CjTsdA than in AvTsdA, possibly because both oxidative and reductive transitions in the former involve only His/Met ligated heme. The peak to trough intensity of ~365 M⁻¹ cm⁻¹ T⁻¹ for the 554 nm feature is consistent with one fully reduced heme and comparable for that deduced for His/Met Heme 2 in AvTsdA.

Anaerobic incubation of CjTsdA with dithionite eliminates the features associated with Fe(III) Heme 1 from the MCD spectrum (Fig. 4C, blue) but produces an increase of ~30% in the peak to trough intensity of the 550 nm feature implying that, as with AvTsdA, protonation of the Heme 1 Cys⁻ accompanies reduction. In contrast to AvTsdA, the MCD of fully reduced CjTsdA contains no intensity at 440 nm that might indicate the presence of high-spin Fe(II) heme.
**Protein film voltammetry of Av and Cj TsdA enzymes.**

Insight into the redox properties associated with the fully equilibrated TsdA proteins is provided by the MCD described above. The redox activities fall in two well-separated regions, conveniently dissected by the potential of approximately +60 mV produced in solution by a 1.5 mM concentration of ascorbate (see Materials & Methods). In both proteins, Heme 1 remains fully oxidized in the presence of ascorbate but is fully reduced by dithionite, implying $E_m$ for the Fe(III)/Fe(II) couple lies in the approximate range −380 to −60 mV. Ascorbate fully reduces Heme 2 in CjTsdA and >80% in AvTsdA, placing the apparent $E_m$ values above $=+100$ mV in both proteins. Greater insight into the redox properties of both TsdA proteins was afforded by cyclic voltammetry after their adsorption on IO-ITO electrodes. These hierarchically structured electrodes (30) offer a large, nanostructured surface area onto which the enzymes adsorb as electrodes (30) offer a large, nanostructured surface area onto which the enzymes adsorb as electroactive films. Cyclic voltammetry reveals peaks (Fig. 5) corresponding to protein reduction (negative currents) and oxidation (positive currents). From these voltammograms, measured at negative currents and oxidation (positive peaks (Fig. 5) corresponding to protein reduction electroactive films. Cyclic voltammetry reveals area onto which the enzymes adsorb as electrodes (30) offer a large, nanostructured surface area onto which the enzymes adsorb as electroactive films. Cyclic voltammetry reveals peaks (Fig. 5) corresponding to protein reduction (negative currents) and oxidation (positive currents). From these voltammograms, measured at negative currents and oxidation (positive peaks (Fig. 5) corresponding to protein reduction (31). These peaks would have equal areas one corresponding to oxidation and the other to reduction. However, the behavior differs from that of CjTsdA in several respects. At high potentials the oxidative peak displayed by AvTsdA is larger than the corresponding reductive peak ($Q_{ox}^{hi} > Q_{red}^{hi}$) and at low potentials the reductive peak is larger than the corresponding oxidative feature ($Q_{red}^{lo} > Q_{ox}^{lo}$). Furthermore, while the peaks at high potential have $\delta = 80 – 100$ mV, indicative of $n = 1$, those at low potential are significantly broader ($\delta = 150$ mV) and each shows structure suggesting two overlapping signals. Indeed, both low potential peaks could be reasonably described by the sum (Fig. 5B, blue open circles) of two contributions.

Heme ligation & redox chemistry in TsdA

At 10 mV s$^{-1}$ the voltammetry of AvTsdA also resolves four peaks (Fig. 5B black) and $Q_{ox}^{red} = Q_{red}^{red}$ (Fig. S3 and Table S3). There is again a disparity between the charge transferred in the peaks at high and at low potentials. However, the behavior differs from that of CjTsdA in several respects. At high potentials the oxidative peak displayed by AvTsdA is larger than the corresponding reductive peak ($Q_{ox}^{hi} > Q_{red}^{hi}$) and at low potentials the reductive peak is larger than the corresponding oxidative feature ($Q_{red}^{lo} > Q_{ox}^{lo}$). Furthermore, while the peaks at high potential have $\delta = 80 – 100$ mV, indicative of $n = 1$, those at low potential are significantly broader ($\delta = 150$ mV) and each shows structure suggesting two overlapping signals. Indeed, both low potential peaks could be reasonably described by the sum (Fig. 5B, blue open circles) of two contributions.
with δ = 84 mV having different $E_m$ values and areas (Fig. 5B, dotted and dashed lines). This behavior was reproduced in consecutive voltammograms.

In view of the MCD, the following interpretation of the AvTsdA voltammetry at 10 mV s$^{-1}$ is proposed. The main contribution to the peaks at low potential (Fig. 5B, blue dotted lines) is assigned to reversible reduction of His/Cys$^-$ Heme 1 with $E_m = -181$ mV. Other features in the voltammetry, at both high and low potentials, are assigned to Heme 2 for which electron transfer drives exchange of the distal ligand as described by anti-clockwise progress round the states in the square scheme of Scheme 1A. At the most positive potentials of the voltammetry AvTsdA is fully oxidized and Heme 2 has predominantly His/Lys ligation. On scanning to negative potentials, reduction of His/Lys Heme 2 occurs with $E_m = -129$ mV (Fig. 5B blue dashed line). On returning to more positive potentials, the low potential oxidation peak is much smaller, representing oxidation of a remnant of His/Lys Heme 2, and a larger oxidation peak is resolved at $E_m = +260$ mV revealing that the majority of Heme 2 is oxidized with His/Met ligation. Thus, it can be concluded that Met displaces Lys as the distal ligand of reduced Heme 2. During consecutive voltammograms the response is essentially the same as that of Fig. 5B so it can also be concluded that Lys displaces Met as the distal ligand to oxidized Heme 2 on the experimental timescale. In support of our proposal, summations of the deconvoluted features attributed to reduction and oxidation of Heme 2 describe transfer of similar numbers of electrons, $n_{ox} = 104$ and $n_{red} = 114$ pmol e$^-$ respectively. Furthermore, the features ascribed to redox transformation of Heme 1 account for transfer of $n_{ox} = 124$ pmol e$^-$. Thus, unlike for CjTsdA, the electroactive populations of Heme 1 and Heme 2 are essentially equal for AvTsdA.

If the equilibrium for the AvTsdA Heme 2 ligand exchange is defined in the direction His/Lys $\rightleftharpoons$ His/Met then $K_{eq}^{red}/K_{eq}^{ox}$, the ratio of the equilibrium constants in the two oxidation states, can be calculated from the reduction potentials in Scheme 1A: a ratio value of $5 \times 10^6$ is consistent with the MCD results that showed the equilibrium lies significantly towards Lys coordination in the Fe(III) and Met coordination in the Fe(II) states of Heme 2. Some insight into the kinetics of this ligand exchange was afforded by the scan rate dependence of the AvTsdA voltammetric response (Fig. S4). At 100 mV s$^{-1}$ a larger proportion of Heme 2 is oxidized with His/Lys ligation than at 10 mV s$^{-1}$; the ratio $Q_{ox}^{red}/Q_{ox}^{ox}$ (Fig. 6B squares & Fig. S4 circles) is $\approx 35\%$ smaller than at 10 mV s$^{-1}$ while $Q_{ox}^{red}/Q_{ox}^{ox}$ (Fig. 6B triangles) and $Q_{ox}$ (Fig. S4) are essentially unchanged. At the higher scan rate there is insufficient time for Met to fully displace Lys as the distal ligand to reduced Heme 2. Because Heme 1 contributes only to $Q_{ox}^{red}$ and $Q_{ox}^{red}$, in the limiting case of full Lys $\rightarrow$ Met displacement at the reduced Fe(II) heme, $Q_{ox}^{red}/Q_{ox}^{ox} \rightarrow 1$. In this study $Q_{ox}^{red}/Q_{ox}^{ox}$ tends to 1, Fig. 6B squares, only at the lowest scan rate of 5 mV s$^{-1}$ indicating that the Lys $\rightarrow$ Met switch at reduced Heme 2 occurs with a rate of $7 \times 10^{-2}$ s$^{-1}$. For the limiting case of full Met $\rightarrow$ Lys displacement at the oxidized Fe(III) Heme 2, $Q_{ox}^{ox}/Q_{ox}^{red} \rightarrow 0$. In this study $Q_{ox}^{ox}/Q_{ox}^{red}$ is $\approx 0$ even at the highest scan rates, Fig. 6B triangles. This indicates the Met $\rightarrow$ Lys switch triggered by oxidation is always complete before re-reduction which places a lower limit of $0.2$ s$^{-1}$ on the rate of this process.

The (limiting) ligand switching rates, when compared to the larger values of $k_{ca}$ (Fig. 1), favor lysine over methionine during rapid turnover such that Heme 2 would remain His/Lys coordinated. The results of our previous spectroelectrochemical study of AvTsdA adsorbed on SnO$_2$ electrodes (8) can be usefully considered in view of the present results. For that study the protein was poised at increasingly negative (+325 to $-650$ mV) and then increasingly positive potentials (−650 to +325 mV) over a period of ~2 hours compared to the 6 minutes of the slowest cyclic voltammogram in this study. Changes in the electronic absorbance measured at the corresponding potentials suggested a fully reversible (Nernstian) redox transformation centered on approximately $-225$ mV and reduction between $+150$ and $-100$ mV of a second center for which re-oxidation commenced above $+300$ mV. We now confidently assign the reversible redox transformation to Heme 1 and the additional signals, evidencing hysteretic redox titration, to Heme 2, such that the observation of ligand switching at AvTsdA Heme 2 is independent of electrode material.

To investigate the origins of the different behaviors displayed by CjTsdA and AvTsdA three previously prepared single-site variants of CjTsdA (5) were studied as described below. First, we consider the properties of the CjTsdA N254K
variant produced to introduce key features of the AvTsdA Heme 2 distal pocket. Then, we consider properties of the CjTsdA C138M and C138H proteins in which the Cys that ligates Heme 1 is replaced by Met and His respectively.

**Spectroscopic and Electrochemical Characterization of CjTsdA N254K.**

As described above, distal ligation of AvTsdA Heme 2 is provided by Lys208 and Met209, Fig. 2. The equivalent residues in CjTsdA are Asn254 and Met255, Fig. S1. MCD and protein film voltammetry of CjTsdA N254K were performed to assess whether replacing Asn254 with Lys, i.e. creating an AvTsdA like distal pocket, would introduce behavior characteristic of AvTsdA, namely, the Heme 2 ligand switching behavior Scheme 1A, and/or equal electroactive populations of Hemes 1 and 2.

For oxidized CjTsdA N254K (Fig. 7A, black) the bisignate MCD feature at 413 nm is indicative of overlapping contributions from distinct Fe(III) hemes since it is asymmetric and broader than the corresponding features for CjTsdA C138M and C138H. The spectrum lacks intensity at 600 – 700 nm showing that neither heme has any high-spin component. The nIR MCD (Fig. 7B, black) is striking since it reveals CT bands for three distinct low-spin Fe(III) forms. The CT band of His/Cys coordinated Heme 1 is clearly resolved at 1250 nm (~45 nm red shifted compared to CjTsdA). The His/Met feature at 1825 nm has an intensity of 0.47 m$^{-1}$ cm$^{-1}$ T$^{-1}$ showing that ~64% of Heme 2 retains His/Met ligation. The prominent band at 1525 nm, not observed for CjTsdA, indicates His/Lys coordination. Assuming that this accounts for the remaining ~36% of Heme 2, and allowing for the underlying side-band from the His/Met form, suggests a normalized intensity for this His/Lys species of ~1.4 m$^{-1}$ cm$^{-1}$ T$^{-1}$. This high value is typical for His/Lys and comparable to that observed for Heme 2 in AvTsdA. Thus, introducing Lys in place of Asn254 in the CjTsdA Heme 2 binding pocket allows Lys to provide the distal ligand of Heme 2 in a sub-population of oxidized CjTsdA N254K. The structure of the Heme 2 pocket, and not simply the amino acid residues, must exert a significant influence on the ligation at Heme 2 in CjTsdA.

Incubation of CjTsdA N254K with ascorbate (Fig. 7A, red) results in loss of MCD intensity in the 413 nm feature and the appearance of bisignate features at 422 and 551 nm corresponding to low-spin Fe(II) heme. The peak to trough intensity of the 551 nm feature is 250 m$^{-1}$ cm$^{-1}$ T$^{-1}$, only 70% of that observed for ascorbate treated CjTsdA, suggesting incomplete reduction of Heme 2. This interpretation is confirmed by the observation of residual CT intensity at 1525 nm (Fig. 7B, red), sufficient to account for ~15% of His/Lys Heme 2. Therefore, and in line with the behavior of Cj and AvTsdA, Lys/His oxidized Heme 2 has a lower $E_m$ than His/Met Heme 2. Incubation with dithionite removes all features associated with Fe(III) heme from the nIR MCD and increases the intensities of the features at 422 and 551 nm (Fig. 7A, blue) in a manner consistent with complete reduction of Heme 1 and Heme 2.

The voltammetry of CjTsdA N254K at 10 mV s$^{-1}$ (Fig. 8AB), as with the MCD spectra, was more complex than for the other proteins but its features can be assigned in light of the previously described behaviors. After initiating the voltammogram at +400 mV (Fig. 8A black), a small reduction peak centered on +200 mV indicates reduction of His/Met Heme 2. Then a larger, broader peak between ~50 and ~300 mV comprises contributions from the reduction of His/Lys Heme 2 and His/Cys Heme 1 and can be modelled as the sum (red circles) of two $n = 1$ processes (red lines). The species reduced in this first scan therefore correspond to those identified by MCD. However, on returning to +400 mV the low potential oxidation peak is smaller than both the preceding low potential reduction peak *and* the subsequent high potential oxidation peak. The latter is larger than the peak describing the initial reduction of His/Met ligated Heme 2. These observations are reconciled if the population of His/Lys Heme 2 undergoes a Lys $\rightarrow$ Met ligand switch on reduction. Thus, on the first voltammetric cycle, the behavior the His/Lys ligated population of Heme 2 in CjTsdA N254K is strikingly similar to that in AvTsdA; on reduction the Lys ligand is displaced by Met.

The first voltammogram for CjTsdA N254K at 10 mV s$^{-1}$, Fig. 8A (black), described above is clearly different to the second and subsequent voltammograms that are all similar and correspond to the steady-state for this scan rate, Fig. 8B (black). In the steady-state response, the high potential oxidation and reduction peaks have equal areas ($Q_n^{\text{red}} = Q_n^{\text{ox}}$) and are well-described by...
reversible transformation of an $n = 1$ center with $E_{m} = +203 \text{ mV}$ that we assign to His/Met ligated Heme 2. Smaller peaks at low potential correspond to reversible transformation of an $n = 1$ center with $E_{m} = -115 \text{ mV}$ that we assign to His/Cys ligated Heme 1. Thus, on the time scale of these experiments in CjTsdA N254K Heme 2 becomes trapped with His/Met ligation in behavior that differs from AvTsdA. Applying the $E_{m}$ values deduced from the steady-state voltammetry to analysis of the first voltammogram yields $E_{m} = -171 \text{ mV}$ for the His/Lys Heme 2 (Fig. 8A, red dashes). With this assignment of the modelled contributions to the first voltammogram it is seen that approximately equal numbers of electrons are transferred to reduce the His/Met and His/Lys ligated populations of Heme 2. Table S3, in accord with their relative populations deduced by MCD of the oxidized protein.

In the 10 mV s$^{-1}$ steady-state voltammograms of CjTsdA N254K the features assigned to oxidation (reduction) of Heme 2 describe transfer of $\approx 130 \text{ pmol e}^{-}$ and those assigned to oxidation (reduction) of Heme 1 describe transfer of $\approx 40 \text{ pmol e}^{-}$. These values were relatively unchanged for steady-state voltammograms recorded for scan rates between 5 and 100 mV s$^{-1}$, Fig. 6A and Fig. S4. Thus, introducing Lys into the CjTsdA distal pocket is not sufficient to produce a voltammogram with features from equal electroactive populations of His/Cys ligated Heme 1 and Heme 2 having either His/Met or His/Lys ligation. As this behavior contrasts to that described for AvTsdA, we studied CjTsdA C138M and C138H to assess the impact of replacing the Cys ligand to Heme 1 with alternate residues that could also provide heme ligation.

Spectroscopic and Electrochemical Characterization of CjTsdA C138M.

The Soret feature at 413 nm in the UV-visible MCD of oxidized CjTsdA C138M (Fig. 7C, black) is narrower, more symmetrical and of greater peak-to-trough intensity ($\approx 330 \text{ M}^{-1} \text{ cm}^{-1} \text{ T}^{-1}$) than the equivalent CjTsdA feature. All these properties indicate the presence of two low-spin Fe(III) hemes that do not have thiolate ligation. The nIR MCD (Fig. 7D, black) appears to contain a single CT feature at $\approx 1770 \text{ nm}$, in the region diagnostic of His/Met ligation. However, the increased width and intensity ($1.1 \text{ M}^{-1} \text{ cm}^{-1} \text{ T}^{-1}$), as compared to the CT feature observed for Heme 2 in CjTsdA, indicate two overlapping bands. The MCD thus shows unambiguously that both hemes have His/Met axial ligation in oxidized CjTsdA C138M and that Met$^{138}$ is an axial ligand to Heme 1. Subtraction of the CjTsdA nIR spectrum, on the assumption that the Heme 2 band remains relatively unchanged, suggests that the new Heme 1 His/Met CT band lies to shorter wavelength at $\approx 1735 \text{ nm}$.

Incubation with 1.5 mM ascorbate removes all significant MCD intensity at wavelengths longer than 600 nm (Fig. 7CD, red) and the spectrum is dominated by features at 425 and 552 nm that have intensities consistent with two His/Met coordinated low spin Fe(II) hemes. Incubation with dithionite produces no further spectral changes of significance. We conclude that ascorbate reduces both hemes of CjTsdA C138M and that methionine ligation is retained on reduction.

Cyclic voltammetry of CjTsdA C138M at 10 mV s$^{-1}$ (Fig. 8C, black line) corroborates the MCD in placing $E_{m}$ values above $0 \text{ V}$ for the hemes in this protein. Peaks corresponding to oxidation and reduction are resolved between $-50$ and $+300 \text{ mV}$ and both have structure indicative of two overlapping contributions. Indeed, each peak is well-described by the sum (blue circles) of two contributions (blue lines), having approximately equal areas, arising from independent $n = 1$ centers with $E_{m}$ values of $\approx +94$ and $\approx +174 \text{ mV}$. Comparison to the properties of CjTsdA suggests Heme 1 has the lower and Heme 2 the higher of these $E_{m}$ values. Integration of the peaks confirmed $Q_{ox} = Q_{red}$ and similar values were resolved for scan rates between 5 and 100 mV s$^{-1}$ (Fig. 6 and Fig. S3). Thus, protein film voltammetry of CjTsdA C138M differs from that of the CjTsdA and CjTsdA N254K proteins in presenting data immediately reconciled with the presence of equal populations of electroactive Heme 1 and Heme 2.

Spectroscopic and Electrochemical Characterization of CjTsdA C138H.

The MCD Soret feature of oxidized CjTsdA C138H (Fig. 7E, black) shows the same general characteristics as CjTsdA C138M. The hemes are again both low spin Fe(III) without thiolate ligation. Alongside the Heme 2 His/Met CT band at 1820 nm, the nIR MCD (Fig. 7F, black) contains a CT feature at 1480 nm characteristic of bis-nitrogenous coordination and indicating that His$^{138}$ has replaced Cys as a ligand to Heme 1. Incubation with ascorbate leads to loss of the
1820 nm feature (Fig. 7F, red) consistent with reduction of Heme 2. In the absence of the sideband to this feature, the 1480 nm band has an intensity of ~1.0 M^−1 cm^−1 T^−1, consistent with one heme and ruling out any significant reduction of His/His ligated Heme 1 by ascorbate. Incubation with dithionite (Fig. 7E, blue) removes all spectral features characteristic of Fe(III) heme and leads to an increase in the peak to trough intensity of the 553 nm feature from 240 to 640 M^−1 cm^−1 T^−1. Thus the contribution from His/Met Fe(II) Heme 2 is approximately 50% of those for His/Met ligated Heme 1 to be considered electroactive His/His ligated Heme 1 to be considered electroactive. However, this aspect of the voltammetry was scan rate dependent, Fig. S3 and Fig. 6. At 5 mV s^−1 all peaks have equal area indicating equal electroactive populations of His/His ligated Heme 1 and His/Met ligated Heme 2; \( Q_{\text{hi}}^{\text{ox}}/Q_{\text{lo}}^{\text{ox}} = Q_{\text{hi}}^{\text{red}}/Q_{\text{lo}}^{\text{red}} = 1 \). At higher scan rates, the number of electrons exchanged with His/Met ligated Heme 2 was unchanged but less electrons were exchanged with His/His ligated Heme 1; \( Q_{\text{hi}}^{\text{ox}}/Q_{\text{lo}}^{\text{ox}} = Q_{\text{hi}}^{\text{red}}/Q_{\text{lo}}^{\text{red}} < 1 \).

Discussion

The complementary information afforded by MCD and PFE has provided comprehensive structural and thermodynamic descriptions of the hemes in the as purified Av and Cj TsdA enzymes. Hemes with three different axial ligand sets are present in the wild type enzymes. One set, the His/Met pairing, occurs in monoheme cytochromes (32,33) and as an electron transfer center in multiheme enzymes, including the SoxAX enzymes that perform the initial step in a thiosulfate oxidation to sulfate (14,29). The \( E_m \) value for the Fe(III) ⇔ (II) couple of Heme 2 in AvTsdA (+266 mV) falls within the +200 to +380 mV range observed for numerous Class I cytochromes that operate as electron shuttles in photosynthetic and respiratory systems. Although \( E_m \) for Heme 2 in CjTsdA (+172 mV) lies below this range, there are precedents for His/Met coordination with values between +60 and +165 mV in several disparate proteins such as cyt. bd, cellulose oxidase, cyt. b_{562} and DosH (34-38). However, compared to His/Met heme ligation, the additional ligand sets of the TsdA enzymes are significantly less common and would imply a degree of specialization.

The His/Cys− coordination found for Heme 1 in the TsdA enzymes is rare and, while the purpose of such ligation is not always clear (39), some examples are suggested to function as redox sensors (40-42), others as receptors or regulators (43-47). Reported \( E_m \) values lie in the range −350 to −160 mV (40-43,47). Considering only the Heme 1 \( E_m \) values, which fall within this low range, it could be concluded that both TsdA enzymes should be biased to perform tetrathionate reduction more rapidly than thiosulfate oxidation. Such a conclusion is clearly at odds with the catalytic properties of the purified enzymes (Fig. 1) and the cellular role of AvTsdA (3). However, prior to the discovery of the TsdAs, His/Cys− centers had also been identified in the active sites of SoxAX enzymes, where they display reversible Fe(III) ⇔ Fe(II) transitions with \( E_m \) values at or below −400 mV (14,29,48). Although these potentials are markedly more negative than those reported here for Heme 1, it has been proposed that conjugation of thiosulfate to the cysteinate ligand, forming a cysteinyll thiosulfate and releasing two electrons, is an initiation step common to SoxAX multiheme enzymes, including the SoxAX (32,33) and as an electron transfer center in multiheme enzymes, including the SoxAX enzymes that perform the initial step in a thiosulfate oxidation to sulfate (14,29). The \( E_m \) value for the Fe(III) ⇔ (II) couple of Heme 2 in AvTsdA (+266 mV) falls within the +200 to +380 mV range observed for numerous Class I cytochromes that operate as electron shuttles in photosynthetic and respiratory systems. Although \( E_m \) for Heme 2 in CjTsdA (+172 mV) lies below this range, there are precedents for His/Met coordination with values between +60 and +165 mV in several disparate proteins such as cyt. bd, cellulose oxidase, cyt. b_{562} and DosH (34-38). However, compared to His/Met heme ligation, the additional ligand sets of the TsdA enzymes are significantly less common and would imply a degree of specialization.

The His/Cys− coordination found for Heme 1 in the TsdA enzymes is rare and, while the purpose of such ligation is not always clear (39), some examples are suggested to function as redox sensors (40-42), others as receptors or regulators (43-47). Reported \( E_m \) values lie in the range −350 to −160 mV (40-43,47). Considering only the Heme 1 \( E_m \) values, which fall within this low range, it could be concluded that both TsdA enzymes should be biased to perform tetrathionate reduction more rapidly than thiosulfate oxidation. Such a conclusion is clearly at odds with the catalytic properties of the purified enzymes (Fig. 1) and the cellular role of AvTsdA (3). However, prior to the discovery of the TsdAs, His/Cys− centers had also been identified in the active sites of SoxAX enzymes, where they display reversible Fe(III) ⇔ Fe(II) transitions with \( E_m \) values at or below −400 mV (14,29,48). Although these potentials are markedly more negative than those reported here for Heme 1, it has been proposed that conjugation of thiosulfate to the cysteinate ligand, forming a cysteinyll thiosulfate and releasing two electrons, is an initiation step common to SoxAX (49) and TsdA (4,6) (in the context of SoxAX and TsdA, -SSO− has been referred to as a “thiosulfonate” modification (5,6,8,50)). Dissociation of the ligand, concurrent with this modification, is likely to raise the heme reduction potential, facilitating transfer of the electrons to the pair of hemes in the respective enzymes. A rise in the \( E_m \) of Heme 1 such that the potentials of both hemes are comparable to that of the tetrathionate/thiosulfate couple would be consistent
with the facile thiosulfate oxidation displayed by both Cj and Av/TsdA with application of only small overpotentials (1). A Cys → Ala substitution at the active site of Starkeya novella SoxAX suggests that the magnitude of this elevation in \( E_m \) could exceed 500 mV (51). The SoxAX and TsdA enzymes would then differ in the nature of the subsequent, and redox neutral, steps during which the -SSO\(^3^-\) moiety of the cysteinyl thiosulfate is transferred either to the cysteinate of the SoxYZ protein in the case of SoxAX or to a second thiosulfate with TsdA. The generally low heme \( E_m \) values we observe for Heme1 are likely to be a straightforward consequence of cysteinate ligation (52,53), while the 200–300 mV difference between SoxAX and TsdA may reflect characteristics of the distal heme, presumed to be Heme 1 lacking the Cys ligand (55) and is typical for Met to Lys substitution (56,57), it is unlikely that the novel lysine ligation in Av/TsdA is present simply to lower the value of \( E_m \). A potential of −129 mV is well within the range that can be achieved using His/His coordination (58,59). While switching Heme 2 to a lower potential may be the purpose of displacing the methionine, the selection of lysine over histidine may assist dissociation. Lability of the lysine ligand is a common characteristic of the limited number of His/Lys coordinated hemes reported to date (60-63). However, in rapid turnover, Heme 2 would remain His/Lys coordinated in Av/TsdA. The retention of an accessible His/Met form appears not to be critical for catalysis. In contrast, Heme2 in Cj/TsdA N254K remains His/Met after the first turnover and this may explain why tetrathionate reduction is not compromised in this variant.

The limiting values we have obtained for the rates of ligand exchange would imply that lysine remains bound during turnover. But the low \( E_m \) value determined for the His/Lys ligand set (−171 mV) precludes reduction by the substrate thiosulfate. The possibility that lysine ligation is in some way responsible for the pronounced directionality of the Av enzyme can also be ruled out since the AvK208N variant displays the same residual tetrathionate reductase activity as the wild type enzyme (4). The exact purpose of the His/Lys ligation at Heme2 therefore remains to be determined.

Before closing, we return to consider the cyclic voltammetry of CjTsdA that suggests His/Cys+ Heme1 has a lower electroactive population than that of His/Met Heme2. This is surprising given that, based on the structure of AvTsdA, a heme edge-to-edge distance of 8 Å is predicted such that fast electron transfer is expected (64). However, there is an indication that heme-heme electron transfer may be more complex in the CjTsdA enzyme from the cyclic voltammetry of CjTsdA C138H. This reveals that, at increasingly high scan rate, the electroactivity of Heme1 is tuned out while that of Heme2 is unchanged in behavior indicative of relatively slow heme-heme electron exchange. Other possibilities can be proposed to account for the voltammetry of CjTsdA, for example Heme 1 exists in a number of forms having different \( E_m \) values and contributing small un-resolved features to the voltammetry. This situation could arise from modification(s) of the Cys+, perhaps relevant to catalysis, although at
present this suggestion appears to be at odds with the MCD ligand assignments.

In conclusion our studies have demonstrated the ability for MCD in combination with PFE to provide chemically detailed descriptions of TsdA redox activity. Our ongoing experiments aim to exploit this approach to better understand the catalytic mechanism(s) and relative activities of the different TsdA family members. For example, to resolve the redox properties of these enzymes in the presence of their natural redox partners, HiPIP for AvTsdA (65) and a monoheme cytochrome c for CjTsdA (3), and with Cys modifications that are proposed catalytic intermediates.

Experimental Procedures

Protein Preparation: WT and variant TsdAs were produced as described in (4) for AvTsdA and (5) for Cj proteins. Recombinant CjTsdA contains the 309 amino acids predicted from Cj_0815 without the signal peptide and with an N-terminus having a Strep II-tag preceded by 250 – 800 nm and J730 for the range JASCO models J810 for the wavelength range spectral curves were recorded using circular dichrographs, Magnetic Circular Dichroism: protein (4).

and for of the three residues preceding the Strep II-tag (5) acids of the such that the predicted mass of the mature protein indicated in the figure legends and were calculated from C8J_0815 without the signal peptide and with Cj-hemes is 37103 Da. Recombinant AvTsdA is comprised of 243 amino acids predicted from Alvin_0091 without signal peptide followed by a C-terminal extension of one additional amino acid and the Strep tag (predicted mass of mature protein 28142 Da with two c-hemes). The amino acids of the Cj proteins are numbered from the first of the three residues preceding the Strep II-tag (5) and for AvTsdA from the first residue of the mature protein (4).

Magnetic Circular Dichroism: MCD spectra were recorded using circular dichrographs, JASCO models J810 for the wavelength range 250 – 800 nm and J730 for the range 800 – 2000 nm. An 8 T magnetic field was generated using an Oxford Instruments Special Spectromag 1000 split coil superconducting solenoid with a 50 mm ambient temperature bore. Samples were exchanged into 50 mM HEPES, 50 mM NaCl at pH 7.0 for spectra in the range 250 – 800 nm and pH* 7.0 for spectra in the range 800 – 2000 nm (pH* being the apparent pH recorded using a glass electrode for a solution prepared in D2O). Sample concentrations were as indicated in the figure legends and were calculated from the absorption Soret maximum (extinction coefficients shown in Table S1). UV-visible electronic absorbance spectra of protein samples were recorded using a Hitachi model 4100 UV-visible-nIR spectrophotometer. Spectra of the oxidized enzymes are for the as prepared samples unless traces of autoreduction were apparent from the absorbance spectra in which case substoichiometric quantities of potassium ferricyanide were titrated into the sample until the spectrum showed the protein be fully oxidized.

Semi-reduced and fully reduced samples for MCD were prepared in a N2 chamber (atmospheric O2 < 10 ppm) by adding small aliquots of concentrated solutions (~100 mM) of sodium ascorbate and subsequently sodium dithionite until no further changes were observed in the absorbance spectrum. Final concentrations of 1.5 mM, both for ascorbate and for dithionite, were sufficient for all samples with the exception of CjTsdA N254K, which required 5 mM dithionite for full reduction. All potentials here, and throughout the manuscript, are quoted versus SHE. Although the reduction potential for the ascorbyl radical anion/ascorbate couple is \( E'' = +330 \text{mV} \), a low concentration of the radical is maintained by rapid disproportionation and consequently ascorbate solutions produce an effective potential in the region of +60 mV (66,67). This was verified here by determining a value of +59 ±12 mV for a 1.5 mM solution of sodium ascorbate, using a combination electrode placed in a solution containing a mediator cocktail (2 µM each) of 3,6-diaminodurene (DAD) (\( E_m = +276 \text{mV} \)), 2-((3-(3,6-dichloro-9H-carbazol-9-yl)-2-hydroxypropyl)(amino)-2-(hydroxymethyl)propane-1,3-diol (DCAP) (\( E_m = +217 \text{mV} \)), 2,6-dichloroindophenol sodium salt hydrate (DCPIP) (\( E_m = +217 \text{mV} \)), phenazine methosulfate (PMS) (\( E_m = +80 \text{mV} \)), phenazine ethosulfate (PES) (\( E_m = +55 \text{mV} \)), juglone (\( E_m = +30 \text{mV} \)), methylene blue (\( E_m = +11 \text{mV} \)), duraquinone (\( E_m = +5 \text{mV} \)), menadione (\( E_m = -70 \text{mV} \)), indigo carmine (\( E_m = -125 \text{mV} \)), anthraquinone-2,6-disulfonic acid sodium salt monohydrate (ADQS) (\( E_m = -185 \text{mV} \)), anthraquinone-2,6-disulfonic acid sodium salt (AQS) (\( E_m = -225 \text{mV} \)), phenosafranine (\( E_m = -252 \text{mV} \)), safranine-O (\( E_m = -280 \text{mV} \)), benzyl viologen (\( E_m = -350 \text{mV} \)) and methyl viologen (\( E_m = -440 \text{mV} \)). At pH 7.0, the concentrations of dithionite used produce potentials in the region of −500 mV (68).
PFE of TsdA: Working electrodes (30) were comprised of inverse-opal indium-tin oxide (IO-ITO) (20 µm thickness, 0.25 cm² footprint (geometrical surface area) and 750 nm pore diameter) on fluoride-doped tin oxide coated glass. Solutions containing 50 – 100 µM protein (50 mM HEPES, 50 mM NaCl, pH 7) and 1.25 mM neomycin sulfate were drop cast onto ice-cold electrodes and left for 20 min before transfer to a N₂ chamber (atmosphere < 10 ppm O₂) where they were rinsed (50 mM HEPES, 50 mM NaCl, pH 7) to remove loosely-bound protein. Experiments were performed in the N₂ chamber employing a 3-electrode cell configuration (69) containing 50 mM HEPES, 50 mM NaCl, pH 7 at 4 °C. Cyclic voltammetry was performed with PGSTAT12 and PGSTAT30 potentiostats (Autolab) under the control of NOVA 1.11 software. Subtraction of an appropriate baseline response from the measured voltammograms, see Figure S2, was performed using the NOVA software prior to data analysis. Protein (Faradaic) responses were fit assuming each redox-active center displays Nernstian behavior (31) for which the oxidative (reductive) peak has the form:

\[ i(E) = \frac{n²F²νΓ₀\exp(nF(E - E_m)/RT)}{RT(1 + \exp(nF(E - E_m)/RT))^2} \]

where \( i(E) \) is current as a function of electrode potential \( E \), \( ν \) the scan rate, \( Γ₀ \) the population of adsorbed redox center, \( R \), \( F \) and \( T \) have their usual meanings and the number of electrons transferred in the half-reaction (\( n \)) is 1. For TsdA hemes, the \( E_m \) values reported below are averages obtained from the corresponding oxidative and reductive peaks.

The MCD spectra of *Cj*TsdA variants N254K (panels A and B), C138M (panels C and D) and C138H (panels E and F), in the fully oxidized state (black traces), following incubation with sodium ascorbate (red traces), and with sodium dithionite (blue traces). Protein concentrations used for the 300 – 650 nm and the 700 – 2000 nm regions were respectively 47 µM and 325 µM; 40 µM and 160 µM; 18 µM and 169 µM. Data recorded at room temperature in 50 mM HEPES, 50 mM NaCl, pH 7 or the same buffer in D$_2$O pH* 7 for nIR MCD.
Figure 8. Representative protein film cyclic voltammograms for adsorbed CjTsdA N254K, C138M and C138H and as indicated. Experimental data (black solid lines) for 10 mV s$^{-1}$ scan rate in 50 mM HEPES, 50 mM NaCl, pH 7, 4 °C. For CjTsdA N254K; 1$^{st}$ scan, summation (open red circles) of three modelled contributions with $E_m$ +203 mV and −115 mV (red dotted lines), −171 mV (red dashed lines). For CjTsdA N254K; steady-state, summation (open blue circles) of two modelled contributions at $E_m$ −115 mV and +203 mV. For CjTsdA C138M summation (open blue circles) of two modelled contributions at $E_m$ +94 mV and +174 mV (blue dashed lines). For CjTsdA C138H summation (open blue circles) of two modelled contributions at $E_m$ −100 mV and +160 mV.
Scheme 1. The redox-linked His/Met ⇌ His/Lys ligand switch at Heme 2 in A AvTsdA and B CjTsdA N254K.
Heme ligation and redox chemistry in two bacterial thiosulfate dehydrogenase (TsdA) enzymes
