46 **Abstract:** Elevated postprandial glucose (PPG) is a significant driver of non-communicable
47 diseases globally. Carbohydrate-rich foods are a major determinant of PPG. Currently there is
48 a limited understanding of how starch structure within a food-matrix interacts with the gut
49 luminal environment to control PPG. We use pea seeds (*Pisum sativum*), as a model-food, to
50 explore the contribution of starch structure, food-matrix and intestinal environment on PPG.
51 Using stable isotope [¹³C] labelled seeds, coupled with synchronous gastric, duodenal and
52 plasma sampling *in vivo*, we demonstrate that maintenance of cell structure and changes in
53 starch morphology are closely related to lower glucose availability in the small intestine,
54 resulting in acutely lower PPG and promoting changes in the gut bacterial composition
55 associated with long term metabolic health improvements. This work offers huge potential to
56 improve the design of food products targeted at moderating PPG and therefore lowering the
57 risk of non-communicable diseases.

58

59

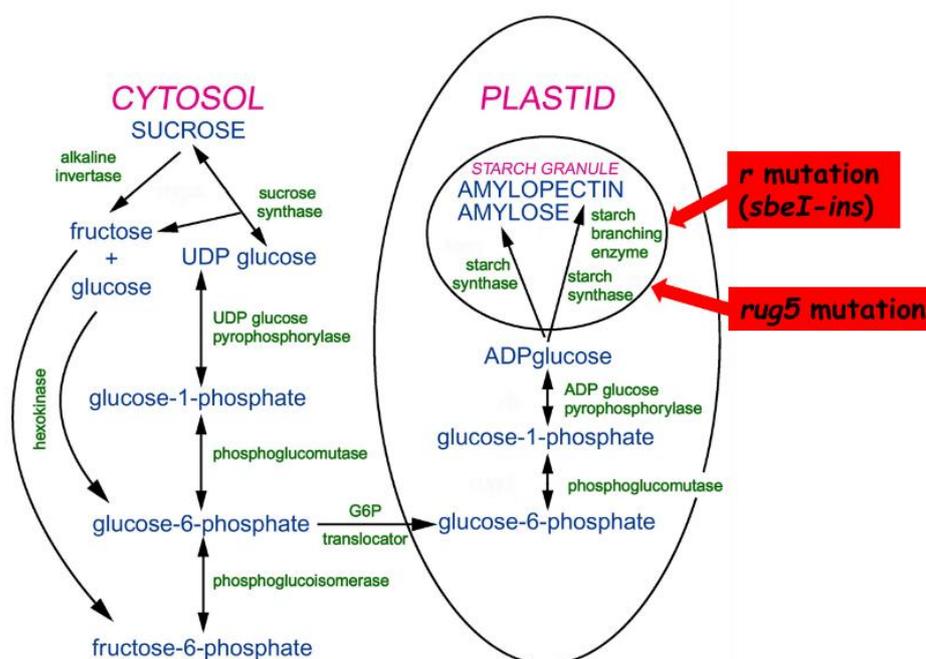

60 **Introduction**

61 The prevalence of non-communicable diseases such as obesity, type 2 diabetes (T2D), and
62 coronary artery disease are rising, representing a major health and financial burden worldwide.
63 Elevated post prandial blood glucose (PPG) is a major risk factor for T2D and associated
64 metabolic diseases (O'Keefe and Bell, 2007). The consumption of carbohydrate rich foods is a
65 major determinant of PPG response (Wolever and Bolognesi, 1996) and glycaemic index (GI)
66 is a method used to rank carbohydrate rich foods according to their impact on PPG (Jenkins et
67 al., 1981). Increasing intake of low GI foods that reduce PPG has been proposed as a successful
68 strategy to improve metabolic health (Jenkins et al., 2002, Greenwood et al., 2013, Jenkins et
69 al., 2008). However, the effect a carbohydrate-based food has on PPG is dependent on many
70 factors such as: the physical structure of food, the type of carbohydrate (e.g., starch and dietary
71 fibre) that it contains, the way the food has been processed and neural and hormonal cues in
72 response to nutrient ingestion. Evidence indicates that the same food can result in different
73 PPG and insulin responses depending purely on processing, for example, as in comparisons of
74 native starch versus retrograded starch (Wang and Copeland, 2013).

75 Here, in a series of experimental studies, using normo-glycaemic volunteers to assess the
76 potential primary prevention impact on metabolic disease, we explore the importance of food
77 structure, carbohydrate quality, and the small intestinal environment on PPG and gut bacteria
78 environment. Throughout, we used mature seeds of pea (*Pisum sativum L.*) as a model food.
79 This crop species shows genetic variation and provides a great opportunity to investigate the
80 impact of starch assembly on digestive processes. Specifically, we used two near isogenic pea
81 lines, which were developed to be near identical genetically except that one line (BC1/19rr)
82 carries a natural mutation in the starch branching enzyme I gene (*SBEI*) (Rayner et al., 2017).
83 In BC1/19RR, the wild-type or control line, SBEI makes a major contribution to the
84 amylopectin (branched starch) fraction present in pea seeds, where the enzyme is active within

85 the plastids of the cotyledonary cells (Fig. 1). The naturally occurring mutation in the *sbeI* gene
 86 (BC1/19rr) is caused by an insertion event which disrupts the carboxy-terminal region of the
 87 protein affecting the structure of the starch and other seed phenotypic traits (Bhattacharyya et
 88 al., 1990, Rayner et al., 2017). This genetic variant has been classified as the *sbeI-ins* allele and
 89 accounted for all *sbeI* mutants within a germplasm resource which was studied (Rayner et al.,
 90 2017). In the mutant line (BC1/19rr), the majority of the starch which is synthesised has been
 91 dubbed ‘resistant starch’, reflecting its largely unbranched amylose polymers and resistance to
 92 digestion. This naturally occurring mutation is unique in *rr* peas however mutations in SBE
 93 exist in other species, mainly induced, such as induce mutation in rice (Sato et al., 2003) and
 94 in durum wheat (Hazard et al., 2012) given the observations made in this series of studies wide
 95 applicability targeting the production and use of commonly consumed foods high in ‘resistant
 96 starch’.

97 In this work, we compared BC 1/19RR wild type and mutant BC 1/19rr peas to examine the
 98 effects of genetic alterations to starch structure on digestion parameters and associated health
 99 outcomes. Additionally, we explore the effects of processing and altered food structure by

100 milling the pea seed to flour and by producing and pea-derived food products; this processing
101 resulted in disruption of the cell wall.

102 **Figure 1. Schematic of the starch biosynthetic pathway in pea seeds adapted from (Wang**
103 **et al., 1998).** The contribution of different enzymes to steps in the cytosol and within the plastid
104 and starch granule are shown in green with the metabolites in blue. The red boxes highlight
105 two mutations affecting enzymes which are active within the starch granule and influence
106 starch structure, of which the naturally-occurring *sbeI-ins* mutation is used in this study.

107 **Results**

108 ***rr* starch genotype and food-structure reduce postprandial plasma glucose and serum**
109 **insulin**

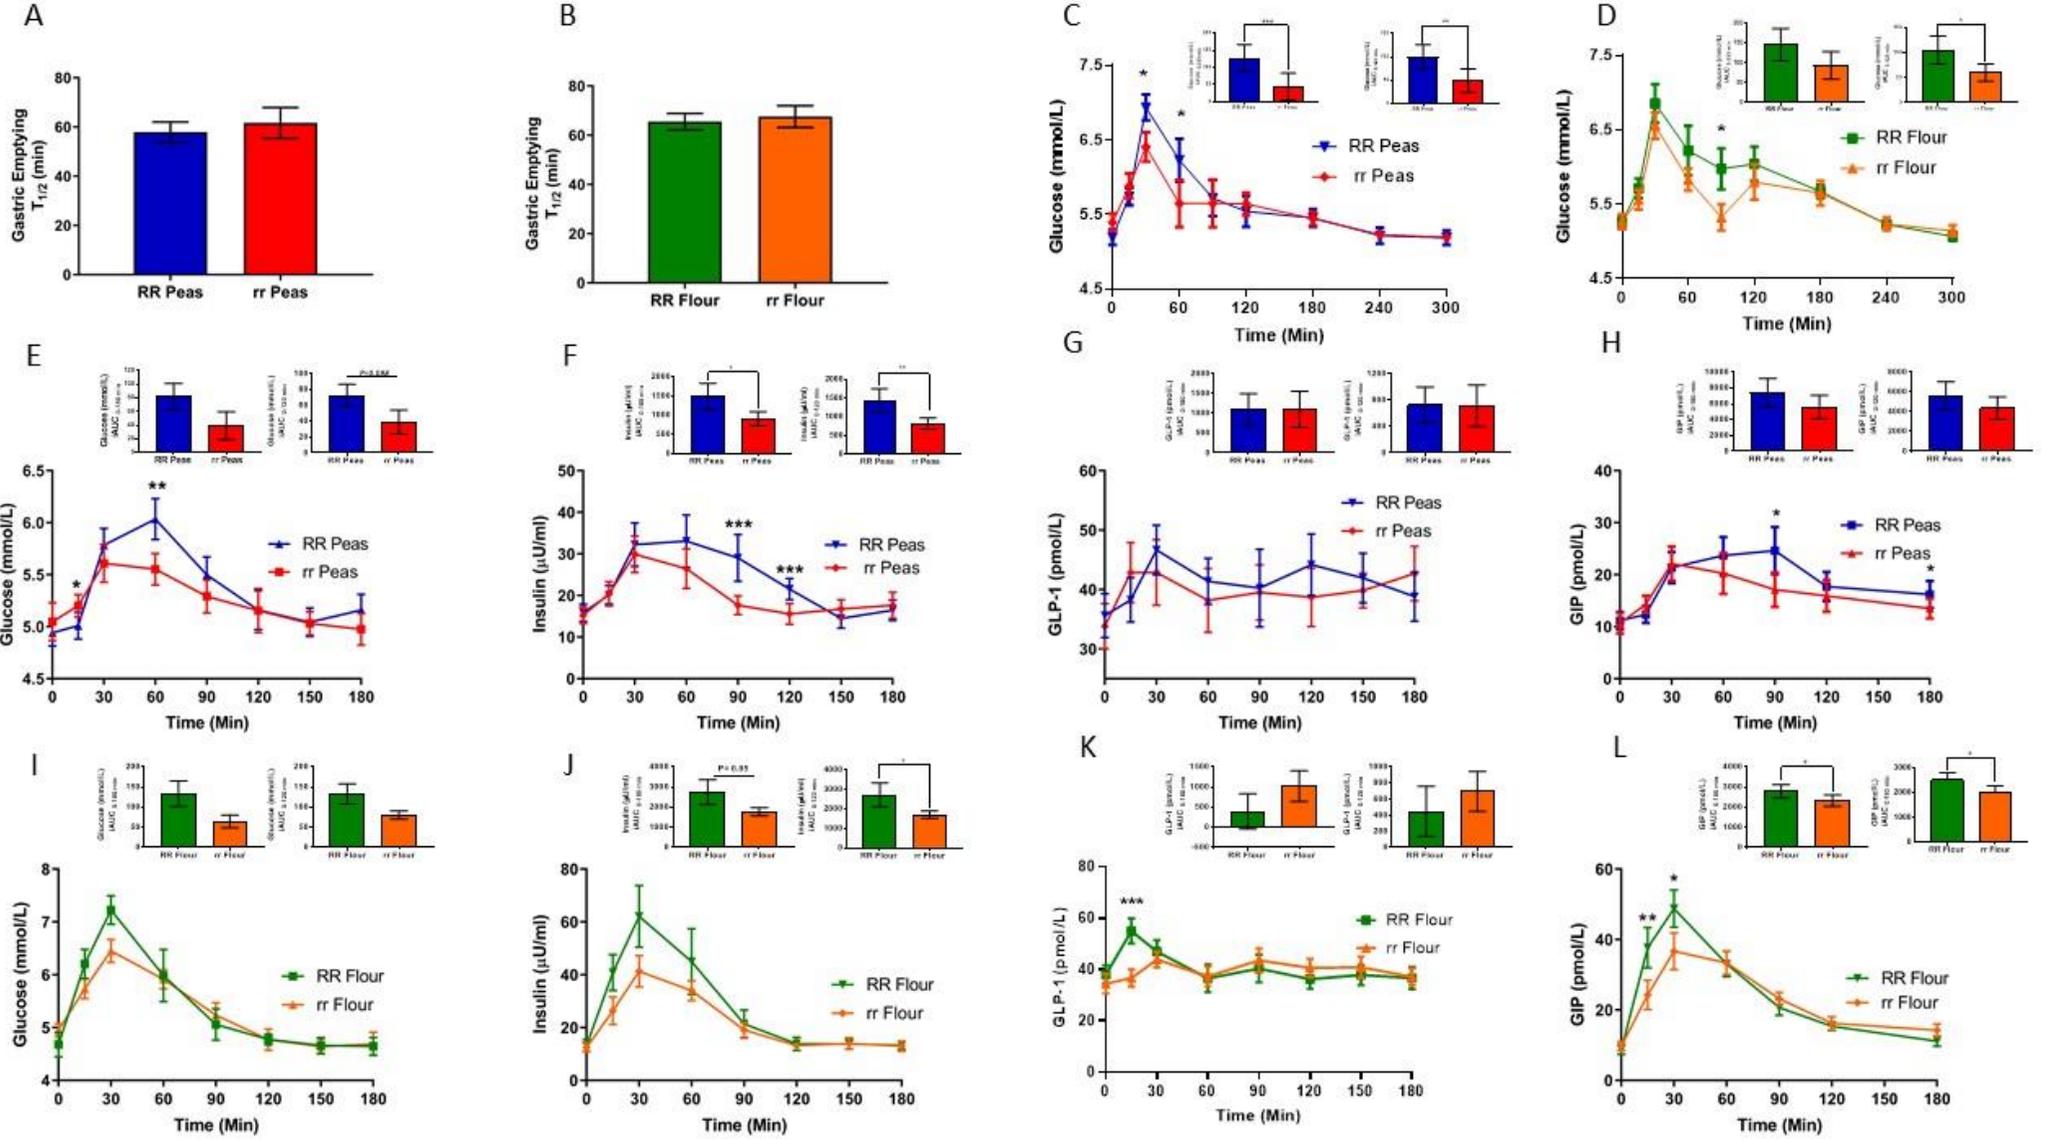

110 We conducted an exploratory study in 10 healthy volunteers to assess the influence of cooked
111 *RR* and *rr* whole pea seeds and flour on gastric emptying and to measure any possible
112 differences, which might influence PPG response. In a mixed meal, we used 50 g dry weight
113 of whole seeds or flour from two pea genotypes (BC1/19RR and BC1/19rr), providing 29%
114 and 26% respectively of the total carbohydrate content of the meal. We assessed solid phase
115 gastric emptying by the [¹³C] octanoic acid breath test (Ghoos et al., 1993). There were no
116 significant differences in baseline characteristics between groups (Table S1). Gastric emptying
117 data for whole seeds and flour, as determined by T_½ (half-emptying time), are shown in Fig.
118 2A, B. There were no significant differences between the seeds (p=0.49) or flour groups
119 (p=0.59) indicating that volunteers began digesting the two different test meals in a similar
120 time course. However, there was a significantly lower PPG for both the seeds and flour meal
121 compared to the *RR* (effect over time, p=0.02, p=0.04 respectively) Fig. 2C, D.

122 Next, to understand the impact of the pea genotype and structure on postprandial glycaemia
123 and insulinaemia we undertook a study in 12 healthy volunteers. The effect of 50 g dry weight
124 *RR* and *rr* seeds and derived flour, as cooked products alone, was tested. This experimental
125 design was a pragmatic approach aimed at representing what a consumer might choose to eat
126 in a real-life meal setting. Volunteer's characteristics are given in Table S2. For whole seeds,
127 plasma glucose and serum insulin concentrations were significantly lower after consumption
128 of *rr* compared to *RR* (effect over time, p=0.02 and 0.001 respectively) (Fig. 2E, F). There was
129 no effect on glucagon-like peptide 1 (GLP-1) (Fig. 2G). The *RR* seeds consumption led to a

130 higher release of gastric inhibitory polypeptide (GIP) compared to *rr* (effect over time, $p=0.01$)
131 (Fig. 2H).

132 With flour, we observed a lower PPG response after consumption of *rr* compared to *RR* that
133 approached statistical significance (effect over time, $p=0.06$) (Fig. 2I). Serum insulin $iAUC_{0-}$
134 $_{120}$ was significantly reduced by 37% ($p=0.04$) for *rr* compared to *RR* (Fig. 2J). During the first
135 15 minutes' post ingestion, there was a higher peak in GLP-1 concentrations observed for *RR*
136 compared to the *rr* group ($p=0.001$) (Fig. 2K). There was also a significantly higher $iAUC_{0-120}$
137 GIP for *RR* compared to *rr* ($p=0.02$) (Fig. 2L).

138 The increase in GLP-1 and GIP in both the *RR* peas and flour tests may be stimulated by the
139 rapid increase in glucose, early in the digestive process. Changes in food structure, induced
140 through processing whole seeds to flour within genotype, showed profound effects on PPG and
141 serum insulin. In both *RR* and *rr*, processing to flour produced a significantly larger glucose
142 and insulin response over 180 minutes (Fig. S1A-D). These observations support a major
143 impact of plant cell structure on PPG and insulin. Together, these data demonstrate that both
144 starch genotype and food structure have an impact on postprandial glycaemia.

146 **Figure 2. The effect of acute consumption of 50 g dry weight *RR* and *rr* pea seeds and flour.**

147 $t_{1/2}$ was determined from the modelled [^{13}C] data in order to describe gastric emptying rates. $t_{1/2}$ was defined as the timepoint at which 50% of exhaled $^{13}\text{CO}_2$ is

148 recovered. (A) Gastric emptying rates for *RR* and *rr* seeds consumption group (n=10). (B) Gastric emptying rates for *RR* and *rr* flour consumption group (n=10).

149 (C, D,) Concentration of plasma glucose for *RR* and *rr* seeds and flour groups during a mixed meal experimental test. (E-H) Concentration of plasma glucose,

150 serum insulin, GLP-1 and GIP measured for 180 minutes for *RR* and *rr* seeds group when fed alone (n=12). (I-L) Concentration of plasma glucose and

151 corresponding serum insulin, plasma GLP-1 and GIP for *RR* and *rr* flour group. Analysis for flour was performed on available paired data, (n=11). Insets show

152 the iAUC between 0 and 300/120 or 180/120 min. The data represent mean \pm SEM. Repeated Measures Anova model was used for testing time course data with

153 pea/flour and time as within-subject factors. Fisher LSD post-hoc tests were performed between timepoints when significant pea/flour \times time interaction was found.

154 Paired *t*-tests were used for iAUCs calculations and gastric emptying data analysis. Timepoints at which values differed significantly, * $p < 0.05$, ** $p < 0.01$,

155 *** $p < 0.001$. Abbreviations: iAUC, incremental area under the curve.

156 **Impact of pea structure and starch assembly on starch digestion**

157 To understand the impact of food structure and pea genotype on PPG and serum insulin
158 observed *in vivo*, we undertook a series of experimental studies *in vitro* to decipher some of
159 the physico-chemical mechanisms of starch digestion and nutrient bio-accessibility in *RR* and
160 *rr* seeds.

161 *Starch digestibility*

162 The total starch contents of whole seeds and flour were determined for both genotypes, at raw
163 state, post-cooking and post-simulated digestion (oral, gastric/small intestinal conditions) (Fig.
164 3A). As expected, the starch content of all samples decreased during simulated digestion. Less
165 starch was digested in whole seeds, (60% for *RR* and 24% in *rr*) (Fig. 3A) indicating that that
166 the starch in *rr* whole seeds was less digestible by the upper GI enzymes than the starch in *RR*
167 whole seeds and corroborates the findings in Fig. 2 (significantly reduced glycaemic response
168 when consuming *rr* peas).

169 After cooking, the portion of analytically resistant starch (ARS) content (Panwar et al.), based
170 on the AOAC 2002.02 method, remained the same in both the *RR* and *rr* flour (Fig. 3B).
171 Surprisingly, in whole seeds, the ARS content decreased in the *RR*, but increased in the *rr* after
172 cooking and digestion. As this was an unexpected increase in ARS for *rr* whole seeds, ¹³C cross
173 polarized magic angle spinning (CP-MAS) NMR was used to establish the helical structure of
174 the starch in uncooked and cooked pea seeds and flour, a key determinant of its resistance to
175 digestion (Fig. 3C & Fig. S2) (Gidley et al., 1995, Lopez-Rubio et al., 2008).

176 The starch in the uncooked *RR* line presented a 35% double helical structure, in both the flour
177 and whole seed (indicating that the starch was not significantly altered during milling), whereas
178 the *rr* line had a lower proportion of double helices (19%), values similar to starch crystallinity

179 values determined previously for *RR* and *rr* pea lines, using x-ray diffraction (Fig 3C)
180 (Bogracheva et al., 1995, Tahir et al., 2010).

181 Following cooking, the flours fully gelatinised, with starches from both genotypes (*RR* and *rr*)
182 having less than 10% double helical order. In contrast to flour, starch from whole seeds of the
183 *RR* genotype only partially gelatinised with a small decrease in double helical order (from 34%
184 to 27%), whereas in the *rr* genotype there was an increase in double helical order observed
185 following cooking (from 20% to 31%). This difference suggests a mechanism for the total
186 starch and ARS analysis and an explanation for the marginal effects observed in PPG and serum
187 insulin concentrations when the *RR* and *rr* flour was given to healthy volunteers, compared to
188 *RR* and *rr* whole seeds.

189 We hypothesized that this process is analogous to annealing where, in the spatially and water
190 limited environment of the plant cell, the starch undergoes structural rearrangements that are
191 different to those in the flour, where the starch is unrestricted in terms of space and access to
192 water. This spatial difference leads to significantly higher levels of ordered structures in the
193 cooked whole seeds relative to cooked flours. These differences may be attributed to
194 differences in the chain length distribution of the *rr* starch (Fig. 3D), which shows that the *rr*
195 starch has far fewer short amylopectin chains (with an R_h of less than 4nm), and a greater
196 proportion of longer amylose chains, which limits swelling of the starch and alters
197 recrystallisation following cooling (Shrestha et al., 2010). The limited swelling and higher
198 ordered structure following cooking (Fig. 3C and F) of *rr* starch as a result of greater long chain
199 amylose leads to a greater proportion of starch escaping small intestinal digestion and reaching
200 the colon where it would be available for fermentation by resident gut bacteria.

201

202 *Impact of the food-matrix on processing and digestion*

203 Simulated digestion experiments revealed that pea seed fragments (> 2 mm) formed from
204 ‘chewing’ during the simulated oral phase remained intact and survived the digestion *in vitro*.
205 Therefore, the size of the particles was measured post-gastric and intestinal phases. Fig. 3E
206 shows that *rr* digesta contained a higher number of larger particles (> 700 μm) when compared
207 to *RR*. A peak in the particle size distribution visible at around 100 μm (peak range 0 - 250 μm)
208 shows that *RR* digesta contained a higher number of smaller particles than *rr* (such as individual
209 cells, free starch and smaller fragments of pea tissue), suggesting that the cell matrix in *RR* was
210 more friable than in *rr*. Interestingly, the size of the fragments did not change significantly
211 during simulated digestion, as the results from the gastric and intestinal phases were similar,
212 so the major impact on the structure was from cooking and the mechanical effect of simulated
213 chewing.

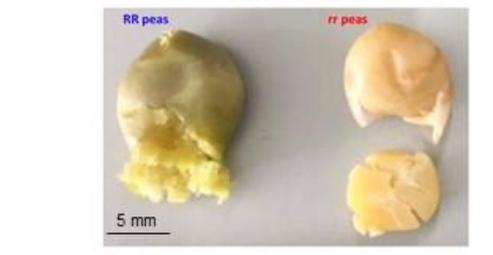

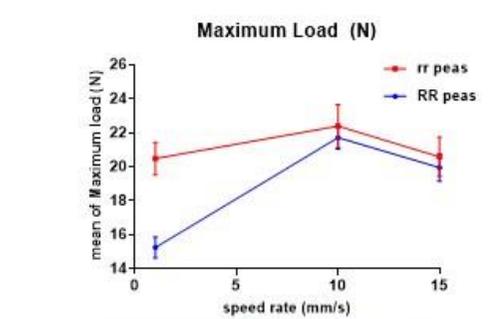

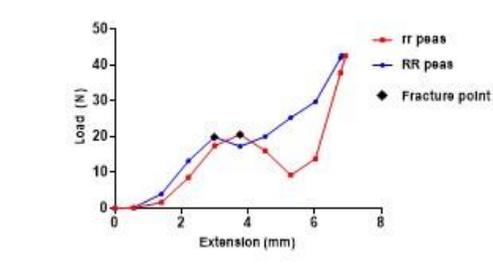

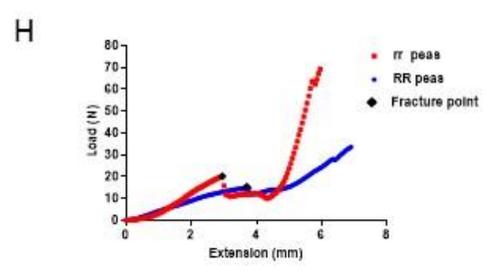

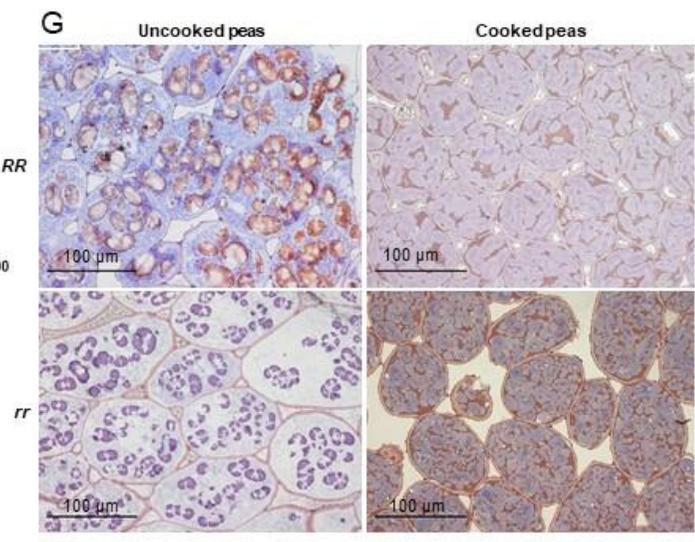

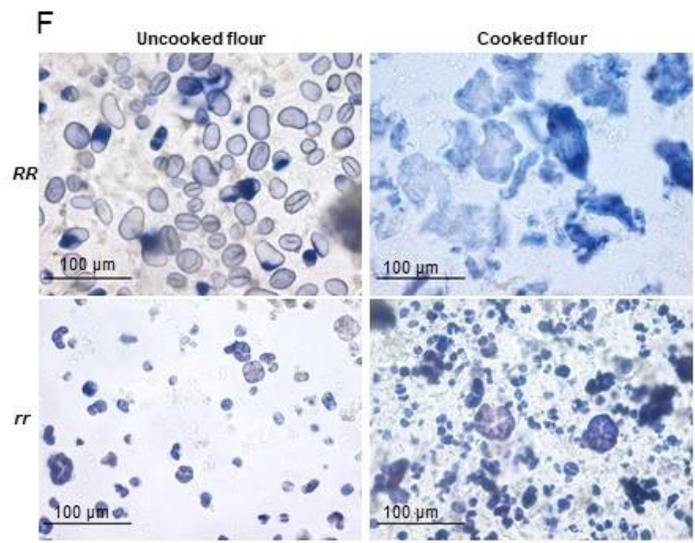

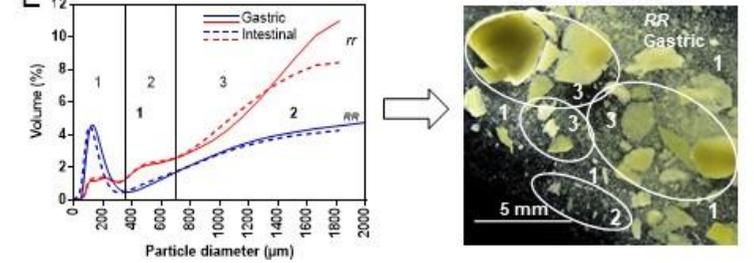

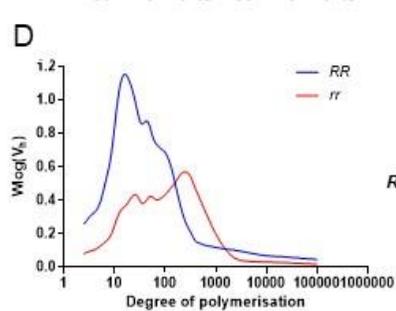

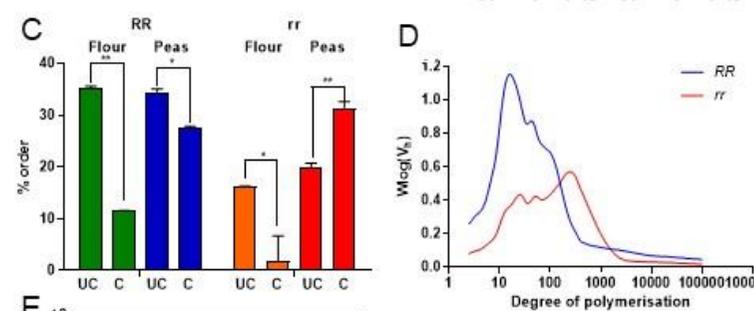

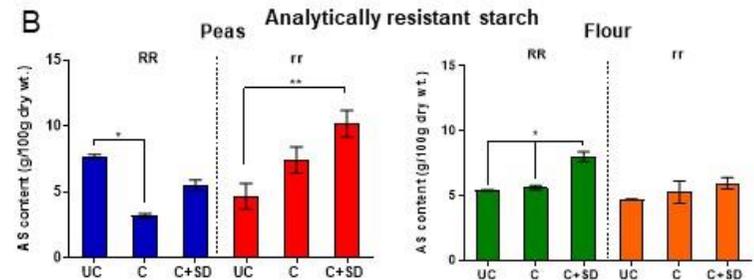

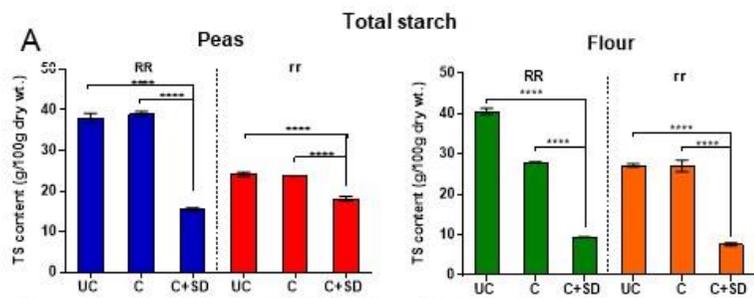

214 The fracture profile of the cooked *RR* and *rr* seeds was investigated to better understand how
215 the structure was affected by mechanical forces. Compression experiments using cooked whole
216 seeds found that force-deformation curves were higher in *rr* compared to *RR* at 1mm/s
217 ($p < 0.0001$) but were similar in both genotypes when the compression rate was increased to
218 15mm/s (Fig. 3H). The *rr* seeds fractured into larger particles of tissue in contrast to *RR*, where
219 they appeared to breakdown completely (Fig. 3H). Although the moisture content for *rr* was
220 higher than for *RR* seeds (60% vs 45%), it was noted that the physical appearance of
221 compressed seeds was different; *rr* seeds tended to split while *RR* seeds were crushed (Fig.
222 3H). The greater resistance of the *rr* seeds to deformation can be explained via the higher levels
223 of insoluble fiber in the form of thicker or stronger cell walls (Skrabanja et al., 1999).

224 Micrographs of seed sections and flour demonstrated the impact of cooking (Fig. 3F, G) and
225 simulated digestion (1 Fig. S3) on the cellular structure and starch morphology. Micrographs
226 of flour (iodine staining) demonstrated the influence of cooking on pea starch following the
227 loss of the pea matrix by milling into flour. The raw starch granules of *rr* were very different

228 in morphology to those of the *RR* genotype (Fig. 3F). The *rr* starch granules were a mixture of
229 simple and compound granules which is an effect of the high amylose content (Zhou et al.,
230 2004). Starch from *RR* flour appeared to be almost fully gelatinized after cooking (Fig. 3F) and
231 was no longer visible after digestion *in vitro* (Fig. S3). Together with the shorter chain lengths
232 in *RR* (Fig. 3D), this probably explains the loss of total starch in *RR* flour following cooking,
233 as the shorter chains probably leached out of the granules and may have avoided detection by
234 the starch assay. However, intact starch granules from *rr* flour persisted throughout cooking,
235 showing many intact, non-gelatinised granules (Fig. 3F) and following digestion *in vitro* (Fig.
236 S3). After simulated duodenal digestion, however, the remaining *rr* flour granules were stained
237 pink rather than blue.

238 Pea seed sections were stained with toluidine blue for protein and iodine for starch
239 identification. After cooking, *RR* starch granules gelatinized to a greater extent than those of *rr*
240 (Fig. 3G cooked), where the starch granules appeared less swollen. In the *RR* peas, starch
241 appeared to be hydrolysed in some cells (where starch is lighter blue/ stained less) and not in
242 others, after digestion *in vitro* (Fig. S3). On the other hand, starch granules in *rr* pea cells, that
243 were less swollen after cooking, appeared undigested within the cells (Fig. S3). Scanning
244 electron micrographs (Fig. S4) of uncooked and cooked seeds confirmed the extent of starch
245 gelatinization within cotyledon cells seen with light microscopy. We observed starch granules
246 to have gelatinized more extensively in *RR* peas and the starch appeared to have a furry texture,
247 which could have formed when the starch expanded into the protein network surrounding it,
248 and/or from amylose that had leached from the starch during cooking, an observation not seen
249 in uncooked samples. In *rr* seeds, the protein network seems thicker and more extensive, the
250 cell walls appear thicker and the interstitial regions have some different structural features,
251 compared to *RR*. All these factors could impact on bio-accessibility and bio-availability during
252 digestion *in vitro* and *in vivo* digestion.

253 Taken together the results show that there are at least two main factors which influence starch
254 digestibility in the pea samples studied. Firstly, the structure and physico-chemical properties
255 of the matrix, the latter of which are plant cell walls in seeds which encapsulate the starch and
256 act as enzyme barriers while also hindering gelatinization of intracellular starch in whole peas,
257 and secondly the intrinsic resistance of the starch granule. The higher amylose content of the
258 *rr* genotype made it intrinsically more resistant to digestion due to its higher ARS content.
259 Even though the *rr* starch in the flour lost much of its order, the morphology of the *rr* starch
260 granules were affected to a lesser extent than *RR* starch following cooking. The matrix thus
261 had an impact on several levels, in that there are marked differences between the *RR* and *rr* pea
262 in carbohydrate profile, which is accentuated by cooking and digestion with differences in cell
263 structure and fracture during digestion.

265 **Figure 3. The impact of genotype structure, and processing on starch digestibility.**

266 (A, B) Total and analytically resistant starch (ARS) contents of uncooked (Zhang et al.), cooked (C) and cooked + simulated digested (C+SD) *RR*
267 and *rr* whole seeds and flours. Structural characteristics of starch in uncooked and cooked flour and whole seeds; helical structure (C), chain length
268 distribution (D). (E) Size of cooked whole seed fragments after simulated gastric and intestinal digestion. Micrographs of uncooked and cooked
269 flours (F) and sections from uncooked and cooked whole seeds (G). Compression experiments (H) using hydrated/cooked *RR* and *rr* whole seeds.

270 * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$. **** $p < 0.0001$

271 ***rr* genotype results in reduced small intestinal glucose release in humans**

272 Since the results *in vitro* showed marked digestive differences between the *RR* and *rr* variants,
273 we then explored the impact of the *rr* mutation on duodenal glucose release in humans. We
274 intubated the small intestine and stomach of 12 healthy volunteers using nasogastric and
275 nasoduodenal tubes. Firstly, we measured the glucose concentration in the small intestine after
276 consumption of pea products (cooked whole pea seeds or flour). Small intestinal glucose
277 concentration for the *RR* group, at 30 minutes, was 3.77 ± 2.28 mmol/L which was nearly two-
278 fold higher than the *rr* group at the same time point (1.92 ± 2.21 mmol/L). We found that, in
279 the *rr* group, small intestinal glucose release was lower and more attenuated during the time
280 course of the study. Results from AUC₀₋₁₂₀ minutes indicated significantly higher small
281 intestinal glucose concentrations for the *RR* compared with *rr* group ($p=0.02$) (Fig. 4B). We
282 found no statistically significant differences in the small intestinal glucose responses between
283 flours from the two pea genotypes (Fig. 4D).

284 *Gastric and Small Intestinal Metabolic Profiles for Whole Pea Seeds*

285 Next, we assessed the gastric and small intestinal metabolic profiles of the aspirated samples
286 using Proton Nuclear Magnetic Resonance (¹H-NMR) spectroscopy. Statistically significant
287 differences were found in the metabolic profiles of gastric samples when comparing *RR* and *rr*
288 pea groups (Fig. 4E). Signals corresponding to the group of metabolites (full list Table S3, S4),
289 amylopectin/maltotriose/maltose, were significantly higher for the *RR* samples at 30 minutes
290 post ingestion compared with those of *rr* ($p=0.0004$, $Q=0.002$).

291 Metabolic profiles of small intestinal samples indicated differences between the two pea
292 groups. We found statistically significant differences in glucose release rates, at 60 minutes
293 post ingestion between the two pea groups (Fig 4F). *RR* seeds resulted in higher glucose release
294 compared with *rr* ($p=0.001$, $Q=0.01$) (Table S5). The data suggests that leaching of

295 amylopectin/maltotriose/maltose from the *RR* seeds makes them more susceptible to early
296 digestion and release of glucose.

297 *Gastric and Small Intestinal Metabolic Profiles for Pea Flour*

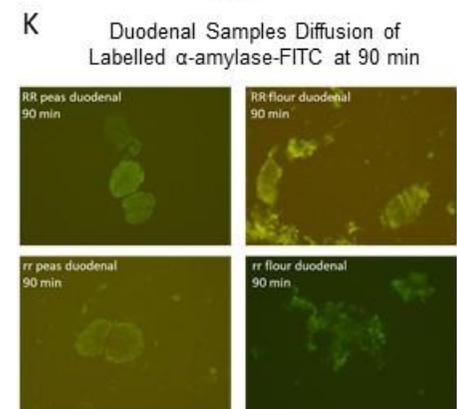

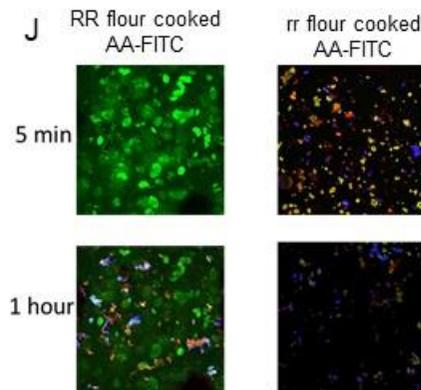

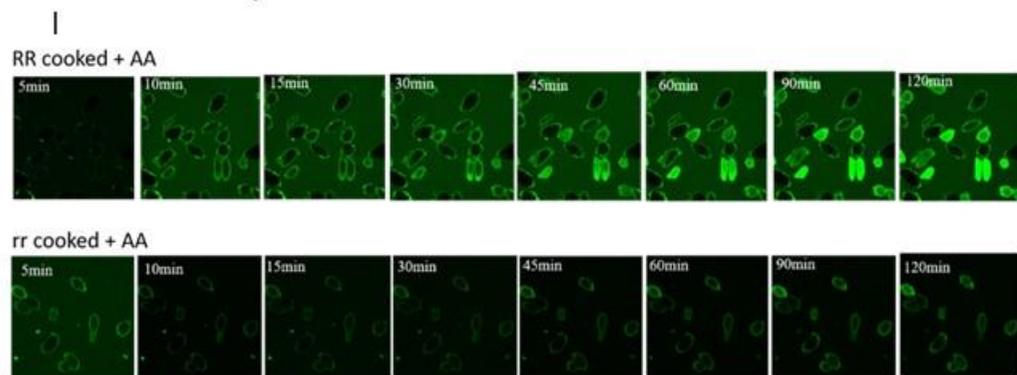

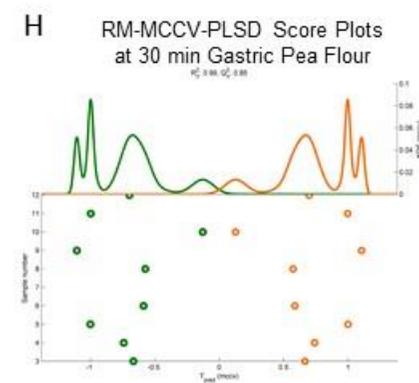

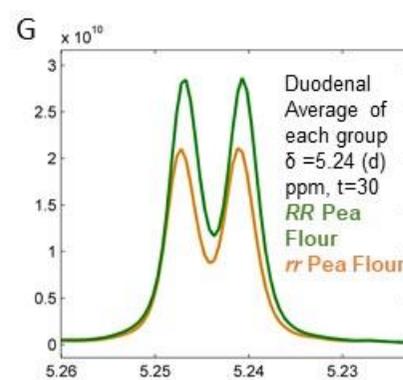

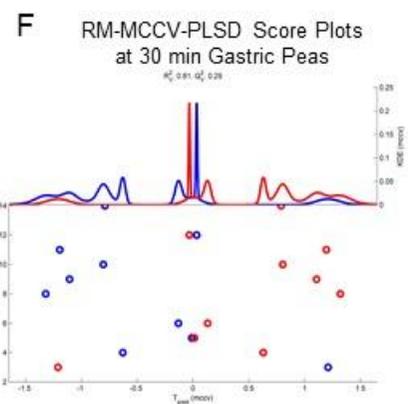

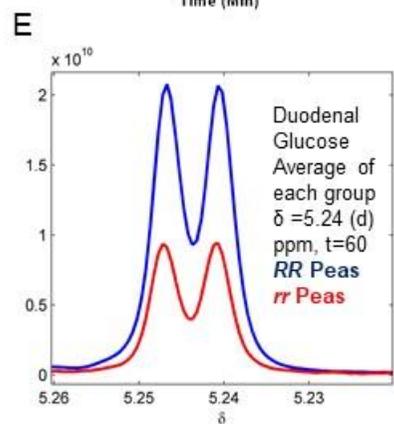

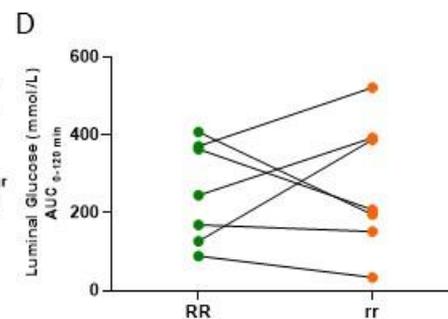

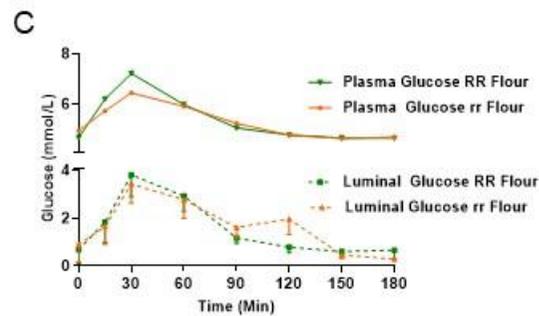

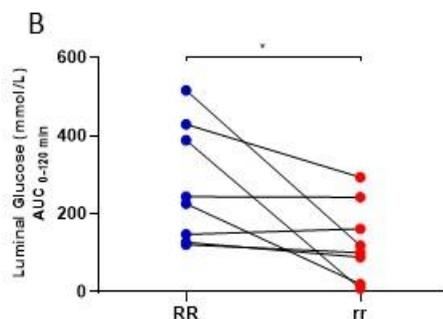

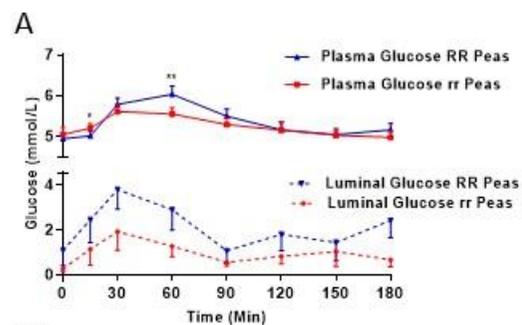

298 ¹H-NMR metabolomic analysis of gastric flour samples indicated differences between the two
299 pea genotypes (Fig. 4G). Similarly, to whole seeds, we found higher
300 amylopectin/maltotriose/maltose in the gastric content of the *RR* flour group at 15- and 30-
301 minutes post ingestion ($p=0.00004$, $Q=0.0019/p=0.0001$, $Q=0.0006$ respectively; Table S6).

302 In the small intestinal samples, the *RR* flour group showed higher glucose concentrations at 30
303 minutes compared to *rr* ($p<0.001$, $q<0.001$) (Fig. 4H). We also observed higher release of
304 sucrose and alanine for *rr* flour compared to *RR* (Table S7).

305 *α-amylase permeability in vitro and ex vivo*

306 We used confocal microscopy to investigate the ingress of amylase into cooked peas and flour.
307 Time course data showed that, within 10 min, FITC-amylase had diffused into the cell walls of
308 both *rr* and *RR* peas (Fig. 4I) but not yet passed into the intracellular space. Further ingress of
309 the enzymes into the intracellular space was slow, as captured by the diffusion constant (given
310 by fluorescence intensity.nm².min⁻¹; 6.19×10^{-10} for *rr* and 1.23×10^{-9} *RR* (summarised in
311 histogram, Fig. S5), and there was heterogeneity in plant cells obtained from *RR*, as seen in the
312 time course (Fig. 4I). For flour, on the other hand, the amylase had bound to the surface of
313 starch granules within 5 min and seemed to progressively erode the starch granules over time
314 (Fig. 4.J). These experiments indicate that the encapsulation of starch by the cell wall obstructs
315 interaction with amylase enzyme. The diffusion of amylase across the intracellular space
316 appeared to be slower for *rr* than *RR* overall.

317 Using the small intestinal digesta from the study *in vivo* we performed experiments *ex vivo*
318 aiming to understand the cell wall permeability to α -amylase (AA) by following the diffusion
319 of AA labelled with FITC (FITC-amylase). In both *RR* and *rr* peas the diffusion of AA-FITC
320 into cells was progressive with time and that the diffusion of AA in *rr* pea samples was slower
321 than in *RR* (Fig. 4K). Uptake of AA-FITC into *RR* and *rr* pea flour was very quick, almost
322 immediate (Fig. 4K).

324 **Figure 4. Small Intestinal Impact on structure and genotype of pea seeds and flour.** (A) Postprandial small intestinal glucose curves for *RR* and *rr* pea seeds
325 along with corresponding plasma glucose, where analysis was performed on available paired data, (n=8). (B) Individual responses expressed as AUC₀₋₁₂₀ for
326 small intestinal glucose for whole seeds (n=8). (C) Postprandial small intestinal glucose curves for *RR* and *rr* flour along with corresponding plasma glucose,
327 analysis was performed on available paired data, (n=7). (D) AUC₀₋₁₂₀ for small intestinal glucose for flour group (n=7). (E) RM-MCCV-PLS-DA scores plots of
328 1D ¹H-NMR gastric samples participants at 30 min after consumption of *RR* vs *rr* seeds (n=10). Model score: R²Y 0.81, Q²Y 0.29. Dots represent the metabolic
329 profile of each volunteer from the study cohort; blue indicates *RR* and red indicates *rr* seeds. (F) Fragment from the average 600 MHz 1D ¹H-NMR spectrum of
330 the *RR* (blue) vs *rr* (red) whole seeds showing the anomeric carbon signal (5.24 (d)) of the glucose molecule. (G) RM-MCCV-PLS-DA scores plots of 1D ¹H-
331 NMR gastric samples comparing participants at 30 min after consumption of *RR* vs *rr* flour. Model score: R²Y 0.99, Q²Y 0.85. Dots represent the metabolic
332 profile of each volunteer from the study cohort; green corresponds to *RR* and orange corresponds to *rr* flour. (H) Fragment from the average 600 MHz 1D ¹H-
333 NMR spectrum of the *RR* flour (green) vs *rr* flour (orange) showing the anomeric carbon signal (5.24 (d)) of the glucose molecule. (I) Diffusion of labelled α -
334 amylase-FITC in cooked *RR* and *rr* peas (green) at different timepoints. (J) Diffusion of labelled α -amylase-FITC in cooked *RR* and *rr* flour (green) at 5 and 120
335 min. (K) Diffusion of labelled α -amylase-FITC at 90 min in duodenal samples in *RR* and *rr* peas and flour.

336 Data are presented as mean \pm SEM. Timepoints at which values differ significantly, *p<0.05, **p<0.01.

337 Abbreviations: AUC (area under the curve), RM-MCCV-PLSD (Repeated measures-Monte Carlo cross validation-Partial-squares-discriminant analysis), AA (α -
338 amylase), FITC (Fluorescein isothiocyanate)

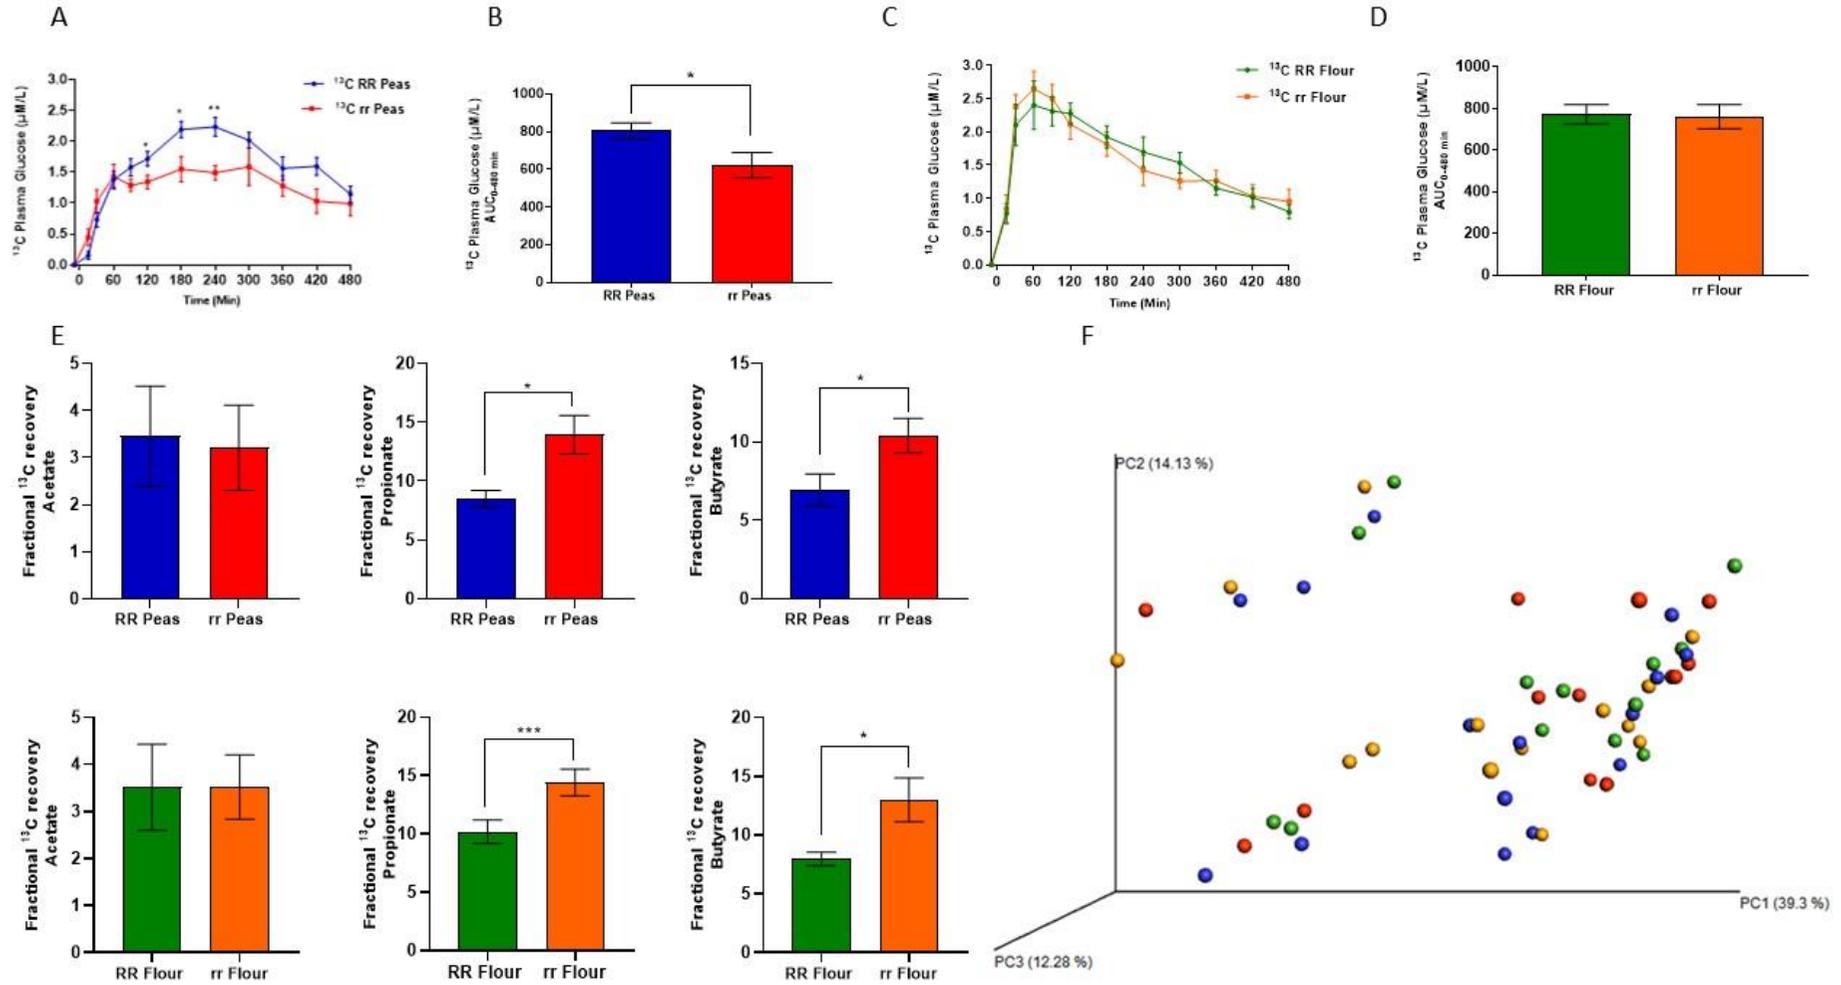

339 ***rr* genotype increases SCFA production**

340 To understand the digestive process further, we labelled both the *RR* and *rr* seeds, with the
341 stable-isotope ^{13}C , by growing them in a $^{13}\text{CO}_2$ enriched environment in a hermetically sealed
342 greenhouse and assessed labelled metabolites in plasma and urine. This procedure produced
343 pea starch with an enrichment of ~ 0.2 atom percent ^{13}C above natural abundance. Volunteers
344 ($n=10$) undertook a randomised cross-over study to investigate ^{13}C glucose and ^{13}C SCFA
345 appearance after *RR* and *rr* seeds and flour consumption (Table S8, volunteer characteristics).
346 The time course and total area under the curve for exogenous ^{13}C postprandial plasma glucose
347 indicated significantly higher concentrations after consumption of the *RR* as opposed to the *rr*
348 seeds test meal (Fig. 5A, B). There was no significant effect observed when comparing *RR* and
349 *rr* flour for exogenous postprandial ^{13}C plasma glucose and total AUC_{0-480} (Fig. 5C, D). These
350 observations support the PPG results observed in the first study (Fig. 2).

351 We measured fractional recovery of ^{13}C SCFA (acetate, propionate and butyrate) in 24-hour
352 urinary collections. ^{13}C acetate excretion did not result in statistically significant differences
353 between *RR* and *rr* in either the seed or flour groups ($p=0.65$). However, ^{13}C propionate and
354 ^{13}C butyrate output was significantly higher after consumption of *rr*, either seeds or flour
355 ($p=0.01$, $p=0.03$, respectively) (Fig 5E). This suggests that, with *rr* test meals, carbohydrate
356 was not fully digested in the small intestine and more was delivered to the colon where it was
357 fermented by the gut microbiota. We investigated whether or not changes in the stool gut
358 microbiome might occur over 24 hours but there was no difference in gut microbiome diversity
359 between the pea genotypes for either test meal (Fig. 5F).

360 These data suggest that the main effect on glucose absorption is the structural barrier of the
361 whole pea which is enhanced by the *rr* genotype. However, the SCFA production highlights
362 that the starch from the *rr* flour was not fully digested in the small intestine. There was no

363 evidence of an acute effect on stool microbiota diversity although we observed an increase in
364 SCFA production with the *rr* genotype in both seeds and flour.

367

368 **Figure 5. Using stable-isotope ^{13}C -enriched *RR* and *rr* pea seeds and flour to understand the digestion and fermentation process further.**

369 (A) ^{13}C plasma glucose curves for *RR* and *rr* groups after administration of 50 g dry weight ^{13}C -enriched whole seeds along with a mixed meal
370 test (n=9). (B) Total AUC_{0-480} of exogenous ^{13}C plasma glucose concentrations for *RR* and *rr* seeds (n=9). (C) Postprandial plasma ^{13}C glucose
371 responses for *RR* and *rr* flour and (D) corresponding AUC (n=8). (E) Fractional enrichment in urinary concentrations of ^{13}C acetate, ^{13}C propionate
372 and ^{13}C butyrate after consumption of ^{13}C -enriched *RR* and *rr* seeds (n=10) and flour (n=9). (F) Gut microbiota weighted beta-diversity plots for
373 *RR* (blue) and *rr* (red) peas and *RR* (green) and *rr* (orange) flour. ^{13}C plasma glucose and urine samples were analysed using gas chromatography-
374 combustion isotope ratio mass spectrometry. Beta diversity analysis was performed using the UniFrac metric calculated with QIIME 1.9.0 and
375 visualized as a 3D principal coordinates analysis plot using Emperor. Data represent mean \pm SEM. Repeated Measures Anova model was used for
376 testing time course data with pea/flour and time as within-subject factors. Fisher LSD post-hoc tests were performed between timepoints when
377 significant pea/flour \times time interaction was found. Paired t-tests were used for AUC calculations. Time points at which values differ significantly,
378 * $p < 0.05$, *** $p < 0.001$. Abbreviations: AUC, total area under the curve

379 **Effect of *RR* versus *rr* pea seed products consumption on glycaemic control**
380 **independently of the food matrix.**

381 To understand the effects of the pea genotype independently of the food matrix on the PPG and
382 gut bacteria we used a randomized, double-blind, crossover control trial in 25 metabolically
383 healthy volunteers aged 40-70 years. Volunteer characteristics and a consort diagram are given
384 in Table S9 and Fig. S6. Volunteers were provided with pea products to consume (mushy-
385 peas/pea-hummus) for 28 days from the *RR* and *rr* lines in random order. They were asked to
386 consume 1 can of mushy peas (120 g) and 1 can of pea hummus (120 g) giving a daily increase
387 of resistant starch of 20 g in the *rr* group. All measurements were performed at baseline (0
388 days) and follow up (28 days) after a 12 h overnight fast. We assessed the effects of repeated
389 pea consumption exposure on stool gut bacteria, glucose metabolism, GLP-1 and lipids. A full
390 summary of all outcome variables can be found in Table S10.

391 *Glucose Metabolism*

392 During the experimental procedure volunteers were given a mixed meal tolerance test without
393 including the interventional pea-derived food product (both groups received the same meal).
394 We found no statistically significant differences in markers of plasma glucose and serum
395 insulin (fasting and postprandial measures) within or between groups (Fig 6A-D). Changes in
396 β -cell function and insulin sensitivity were assessed by using the Homeostatic Model
397 Assessment 2 (HOMA 2). We observed no differences within or between groups.

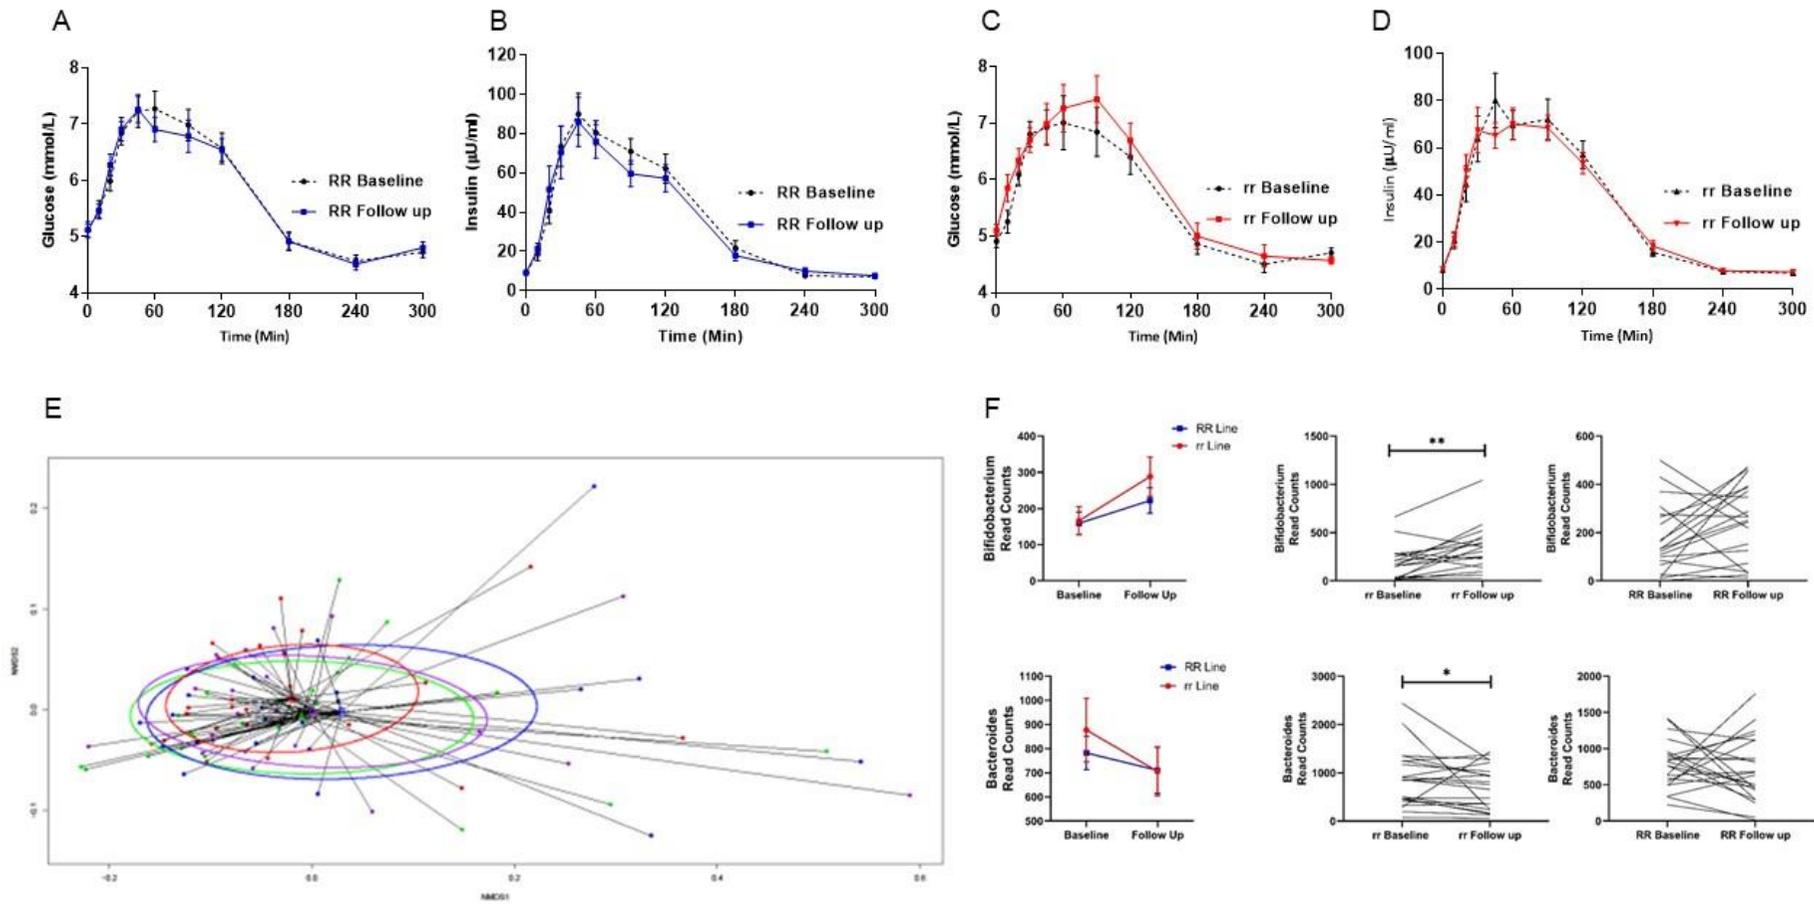

398

399 .

400 *Gut Microbiome 16S rRNA Gene Sequencing*

401 No statistically significant effect in the clustering within or between *RR* or *rr* interventions
402 (within *RR*: $p=0.83$, within *rr*: $p=0.92$; between interventions: $p=0.92$) was observed (Fig. 6E).
403 Due to high inter-individual variability we examined the data as paired samples per volunteer
404 and looked specifically for gut bacteria related to insulin resistance. Within the *rr* intervention
405 group, at genus level, there was a decrease in the relative proportion of *Bacteroides* ($p=0.04$)
406 and an increase in the relative proportion of *Bifidobacterium* ($p=0.007$) between baseline and
407 follow up (Fig 6F). Within the *RR* intervention group, results indicated a statistically significant
408 decrease in *Lachnospiraceae* and *Ruminococcaceae* ($p=0.01$, $p=0.004$ respectively), which are
409 known as starch degraders. Between groups (*RR* and *rr* interventions), a statistically significant
410 decrease in the relative abundance of *Collinsella* was observed after 28 days of *rr*
411 supplementation ($p=0.03$). Previous studies have reported increased levels of *Collinsella* in
412 individuals suffering from T2D (Lambeth et al., 2015)

413 These data suggest that exposure to *rr* pea-derived products leads to positive changes in the gut
414 bacteria associated with glycaemic control. However, there was no associated measurable
415 impact of the genotype on blood glucose parameters in metabolically healthy volunteers over
416 the relatively short 28 days supplementation period.

418 **Figure 6. The effect of consuming products derived from the two pea genotypes for 28 days on glucose homeostasis and gut microbiota.**
419 (A) Postprandial plasma glucose for *RR* and *rr* lines (B) and serum insulin responses: *RR* (C), *rr* (D). (E) Nonmetric multidimensional scaling
420 (NMDS) plots for *RR* and *rr* pea interventions before and after the consumption of pea derived food products. *RR* visit 1; , *RR* Visit 2 , *rr*
421 Visit 1 , *rr* Visit 2 . Analysis was performed on available paired data (n=22). Subsample read counts for Bifidobacterium and Bacteroides
422 for both lines of peas (F).

423 Discussion

424 Drawing on insights from basic plant science and genetics, in this paper we provide novel
425 insight on the impact of starch quality and food-matrix on human health, via the mutation at
426 the *r* locus which results in a defective starch branching enzyme in *rr* compared with *RR* wild-
427 type pea. The impact of the mutation on SBE activity results in differences in starch granule
428 formation and digestion properties, leading to higher resistant starch content in the *rr* pea. We
429 demonstrated that whole seeds and flour from the *rr* genotype made a significant impact on
430 glucose and insulin homeostasis compared to the *RR* wild type and the most marked effect was
431 seen when the cellular structures remained intact during digestion. Despite the fact that the
432 difference in PPG between the *RR* and *rr* flour is less marked, we were able to observe a greater
433 increase in fermentation in the case of *rr* flour. These observations align with other studies
434 where bio-accessibility has been reduced in wheat endosperm with a concomitant decrease in
435 PPG (Edwards et al., 2015). Recent reports have suggested that the starch granule of the *rr* seed
436 has an outer layer of amorphous starch which is rapidly digested and an inner core of crystalline
437 starch (Edwards et al., 2018). Others have shown that the initial rate of amylase digestion is
438 the same between the genotypes, but decreases in the *rr* genotype over time (Tahir et al., 2010).
439 It is possible that the lack of clear effect on blood glucose, in the case of flour, is related to the
440 time in the duodenal space, which in humans is less than two hours. A possible explanation for
441 these observations is that the amorphous starch in both genotypes is digested at the same rate
442 during the time they are resident in the duodenum, and the resistant starch inner core, which is
443 higher in the *rr* seed, is unaffected and delivered into the colon. We have demonstrated using
444 direct measurements of glucose in the duodenum in humans that the availability of
445 carbohydrate in the small intestine directly relates to plasma glucose concentrations. The more
446 resistant starch structures in the whole *rr* seeds led to lower duodenal and lower PPG with a
447 greater transfer of carbohydrate to the large bowel.

448 It is of interest that the higher availability of glucose in the duodenum from *RR* seeds is
449 associated with an increased release of GIP that relates to higher plasma insulin levels. This
450 increase is also reflected in the *RR* flour with higher post prandial levels of GIP and GLP-1
451 related to an increase in post prandial insulin. Duodenal glucose infusions in humans have
452 shown similar findings with high concentrations and flow rates of glucose in the duodenum
453 increasing both GLP-1 and GIP concentrations in the plasma (Pilichiewicz et al., 2007).
454 Although we did not observe a significant difference in direct measures of duodenal post
455 prandial glucose in the flour group, the NMR analysis suggests a higher duodenal glucose at
456 30 minutes. We conclude that postprandial insulin concentrations are higher in the *RR* whole
457 seeds and flour and this is driven through a higher availability of glucose in the small intestine
458 and the stimulation of the incretins, GIP and GLP-1. The reduction in duodenal glucose and
459 PPG in the face of lower insulin release but an increase in colonic fermentation in the *rr*
460 genotype would appear to be solely due to an increase in starch reaching the colon.

461 A series of experiments *in vitro* and *in vivo* demonstrated the complex multifactorial nature of
462 the increased delivery of starch to the colon in the *rr* genotype. Firstly, the cooked *rr* seeds
463 appear more resistant to fracture and during simulated gastric and duodenal digestion the size
464 of the particle population remained larger reducing the surface area for amylase activity
465 (Edwards et al., 2015, Edwards et al., 2018). Secondly, the metabolomic profiling of the
466 aspirated gastric and duodenal samples indicated differences between the two genotypes in the
467 amylopectin/maltotriose/maltose concentrations during digestion. It is known that amylopectin
468 is more readily digested than amylose and that amylose is a poor substrate for pancreatic α -
469 amylase (Zhang et al., 2006). Therefore, by identifying higher concentrations of these
470 metabolites in the digesta from the *RR* genotype it would suggest that the greater fracturing of
471 the food matrix in the *RR* genotype leads to increase in digestible carbohydrate in the
472 duodenum. Thirdly, we demonstrated that the complex nature of starch digestion and the size

473 and morphology and physical chemistry of starch granules (helix ordering and chain length)
474 are more accurate predictors of glycaemic response than simply amylose content of the seed.
475 For example, we demonstrated that cooking *rr* whole seeds increased amylose double helix
476 starch structure, creating resistant starch that is not seen in *RR*. This process has been
477 demonstrated to increase resistance to amylase previously (Gidley et al., 1995). Our data also
478 suggest that the penetration of α -amylase into *rr* cells is lower and slower than in *RR* not only
479 in the samples digested *in vitro* but in duodenal samples from humans *in vivo*, similar to
480 observations made in ileostomy participants using wheat flour and particles (Edwards et al.,
481 2015). The studies *in vitro* clearly align with the stable isotope experimental studies *in vivo*
482 which demonstrate a reduced absorption of carbohydrate in the small intestine with an increase
483 in bacterial fermentation in the *rr* compared with the *RR* group, as judged by fractional recovery
484 in 24-hour urinary ^{13}C SCFA propionate and butyrate profiles. SCFAs, particularly butyrate,
485 are associated with numerous health benefits (Donohoe et al., 2011). There was no detectable
486 change in the stool 16S profile in the *rr* compared to the *RR* group at 24hours despite the
487 increase in SCFA production. This suggests an increase in microbial carbon flux from the
488 enrich carbohydrate colonic environment of the *rr* peas without an acute proportional change
489 in microbiota species compared to *RR* peas. This effect was observed in both seeds and flour
490 from the *rr* line highlighting the importance of the mutation on the starch compositional profile
491 regardless of the food matrix, processing and preparation. These observations highlight the
492 multicomponent aspect leading to reduced duodenal glucose.

493 Observations from the 28-day supplementation study, involving normo-glycaemic individuals,
494 demonstrated positive changes in the gut microbiota with an increase in the proportion of the
495 genus *Bifidobacterium* follow supplementation of the *rr* genotype. Studies have shown that
496 *Bifidobacterium* abundance increase with enriched carbohydrate environment and has been
497 associated with improvements and maintenance of metabolic health (Panwar et al., 2013). The

498 relatively short supplementation period coupled with the healthy cohort of volunteer used may
499 explain why the changes in gut bacteria did not translate into improvements on markers of
500 glucose homeostasis measured. It could be of interested to perform these experiments over
501 longer duration and with individuals with impaired glucose tolerance or type 2 diabetes.

502 Our data shows that the impact of the contrasting genotypes on PPG it is due to complex
503 differences in starch structure and food matrix and their impact on cooking and digestion.

504 These observations could be used to inform the production of modified food types, either
505 through the selection of digestion resistant starch phenotypes or altered food matrices with an
506 aim to chronically lower PPG, which could reduce the number of individuals developing
507 metabolic diseases at a population level.

508 Recent work on SBE genetic mutation has recently induced in staple crops such as rice and
509 wheat, giving these results potential wide applicability, giving this work direct translation. With
510 modern genetic and genomic tools, the discovery or generation of SBE mutations across a
511 number of seed and grain crops provides great potential for expansion of such food products to
512 tackle a major disease.

513 **Materials and Methods**

514 Food Materials

515 The food materials used during the experimental procedures are listed below:

- 516 1. Wild type pea seeds (BC 1/19RR line), used as control group
- 517 2. Mutant pea seeds (BC 1/19rr line), used as the treatment group
- 518 3. Wild type pea flour (BC 1/19RR line), used as control group
- 519 4. Mutant pea flour (BC 1/19rr line), used as treatment group
- 520 5. Wild type pea hummus and mushy peas (BC1/19RR line), used as control group
- 521 6. Mutant type pea hummus and mushy peas (BC1/19rr Line), used a treatment group.

522 The near-isogenic lines of pea (BC1/19RR, BC1/19rr) are available from the John Innes Centre
523 Germplasm Resources Unit as accessions (JI3316 = *RR*, round-seeded, JI3317 = *rr*, wrinkled-
524 seeded; <https://www.seedstor.ac.uk>). Bulk seed stocks were generated by growing plants on
525 wire in field plots over successive seasons (March – July). The resulting seed stocks were used
526 for studies *in vivo* and *in vitro* and supplied to the University of Glasgow for ¹³C labelling and
527 Campden BRI to produce the pea derived products. Campden BRI developed as provided the
528 two pea products the long-term study.

529 ¹³C labelling of pea seeds: seeds were sown in troughs in a glasshouse at the James Hutton
530 Institute, Dundee. The plants developed well and were pulse labelled with ¹³CO₂ one week
531 after flowering. The mature seed was collected and air dried. A sub-sample of each variety was
532 milled to a fine flour and analysed for crude protein, C:N ratio, total ¹³C and starch ¹³C. The
533 yield of the wild type was 1.24 kg at 0.242 atom % ¹³C excess, as measured by EA-IRMS at
534 SUERC. The yield of the *rr* mutant was 1.26 kg at 0.133 atom % ¹³C excess

535 Human Clinical Trials

536 Volunteers

537 All volunteers were provided with informed written consent forms prior to their participation
538 in the 4 human clinical trial studies. All studies were approved by the South East Coast – Surrey
539 Research Ethics Committee (15/LO/0184) and carried out in accordance with the Declaration
540 of Helsinki. Volunteers were recruited via a healthy volunteer's database and public
541 advertisement. For the exploratory studies 1, 2 & 3 men and women aged 18-65 years old, with
542 a body mass index (BMI) of 18.5-29.9 kg/m² were recruited. For the 28-days study (study 4),

543 men and women 40 to 70 years old were recruited with same BMI as in studies 1, 2 & 3.
544 Exclusion criteria for all studies included the following: weight gain or loss >3 kg in the
545 previous 2 months, any chronic illness or gastrointestinal disorder, history of drug or alcohol
546 abuse in the previous 2 years, use of antibiotics or medications likely to interfere with metabolic
547 variable measured, smoking. All study visits took place at the National institute for Health
548 Research/Wellcome Trust Imperial Clinical Research Facility, Hammersmith Hospital,
549 London, United Kingdom and were conducted between May 2015 and December 2017.
550 Randomization for all studies was generated by sealed envelope (Sealed Envelope Ltd,
551 London, UK). In all human clinical studies volunteers were asked to consume the same
552 standardized meal the evening before each study visit and avoid caffeine, alcohol consumption
553 and strenuous exercise for 24 h before the experimental procedure. They were advised not to
554 start any other new diets or intensive exercise regimes during the study period. Weight, height
555 and body fat measurements were collected by using bioimpedance analysis (BC-418 Analyzer;
556 Tanita UK).

557

558 Study 1-Study Day Protocol

559 This study was a randomized, controlled, double blind, cross-over trial. 10 volunteers were
560 recruited for the study and attended 4 study visits (≥ 7 days apart) after an overnight fast.
561 Volunteers received a standardized test meal (0 min) with 50 gr dry weight of *RR* or *rr* pea
562 seeds/flour in a random order. The test meal included 1 slice of white bread, 280 g tomato soup,
563 10 g butter and 1 microwaved egg with 100 mg ^{13}C -octanoic acid (Sercon Ltd, Crewe, UK)
564 being injected in the yolk (378 kcal; 39 g carbohydrate, 18.6 g fat 12 g protein and 2.7 g fiber).
565 50 g dry weight of pea seeds were soaked the day before in 200 ml of water and they were
566 boiled the next morning for 1 hour in 1.8L of water. The pea seeds were added to the tomato
567 soup along with the egg which contained 100 mg ^{13}C octanoic acid. 50 g of dry weight flour
568 was added to the tomato soup and was microwaved for 2 minutes. The flour and pea soup were
569 then mixed with the egg which contained 100 mg ^{13}C octanoic acid. ^{13}C -octanoic acid breath
570 test is a non-invasive, reproducible, stable isotope method for measuring solid phase gastric
571 emptying. By measuring the level of $^{13}\text{CO}_2$ that appears in breath samples following oxidation
572 of the absorbed tracer, we were able to calculate how quickly the stomach empties after eating.
573 Breath samples were taken every 15 min until the end of the study day (300 minutes). The
574 breath test poses no risk to the volunteers and involves blowing through a straw into an
575 Exetainer (Labco Co., High Wycombe, UK) until vapour condensed at the bottom of the tube.
576 Analysis of breath $^{13}\text{CO}_2$ enrichment was by continuous flow isotope ratio MS (AP2003, UK).

577 Study 2-Study day Protocol

578 Twelve healthy volunteers were recruited for this randomized, controlled, double blind, cross
579 over study. Volunteers had to attend the Clinical Research Facility for 4 consecutive days (3
580 nights). Nasogastric and nasoduodenal feeding tubes were placed to allow aspiration of samples
581 from the stomach and small intestine. The enteral feeding tubes were placed by a doctor using
582 the CORPAK (MedSystems, Halyard UK) feeding tube model that tracks the position of the
583 tube during placement without the need for x-rays. The tubes remained in place for the duration
584 of the 4-day visit. An intravenous cannula was inserted into one arm for blood sampling of
585 plasma, serum and gut hormones. Each morning, fasting blood samples and gastric content
586 samples were taken at -10 and 0 minutes. In random order, volunteers received at 0 min, a
587 portion of 50 g dry weight *RR or rr* pea seeds and/or flour. Post prandial blood samples were
588 collected at 15, 30, 60, 90, 120, 180 minutes.

589 Pea seeds and flour preparation: 50 g of dry weight peas and flour were soaked in 200ml of
590 water 24 hours before each study visit. The morning before each study visit peas were boiled
591 for 1 hour in 1.8 L of water. Flour was boiled for 40 min in 800 ml of water.

592 Study day Protocol – Study 3

593 Ten healthy volunteers were recruited for this randomized, controlled, double blind, cross over
594 study and attended the research facility 4 times (≥ 7 days apart) after an overnight fast.
595 Volunteers received a test meal (0 min) which contained 50 g dry weight ^{13}C pea seeds/flour
596 in random order. The test meal included 1 slice of white bread, 280 g tomato soup, 10 g butter
597 (300 kcal; 39 g carbohydrate, 13.6 g fat, 6 g protein and 2.7 g fibre). Throughout the study
598 volunteers were collecting urine samples and were advised to keep collecting their urine
599 samples until the following morning (24 hours). The following morning, they returned to the
600 research unit with the urine sample and a stool sample.

601 Pea seeds and flour preparation: 50 g dry weight peas were soaked in 200 ml of water 24 hours
602 before the study visits, as in previous studies, and were boiled for 30 minutes the following day
603 in 1.8L of water. 50 g dry weight of flour was added to the soup and was microwaved for 2
604 minutes as in previous studies.

605 Study day Protocol – Study 4

606 Twenty-five volunteers were recruited for this randomized, controlled, double blind, cross over
607 study and attended the research facility for 4 visits. Volunteers had to undergo two separate 28-
608 day supplementation periods and they were provided with mushy peas and pea hummus
609 products (*RR* or *rr* line). Before and at the end of each 28-day supplementation period they
610 attended the research facility for a study visit. At time (0) volunteers received an ENSURE
611 drink (Ensure Vanilla Nutrition Shake, Abbott; 330ml, 66.6g carbs, 20.5g protein and 16.2g
612 fat) consisting of 500 kcal. Blood samples were collected throughout the time course of the
613 study (5 hours). Urine samples were collected for the same time frame. Volunteers had to
614 collect a stool sample the day before each study visit. There was a 28-day washout period
615 between the two supplementation periods.

616 ¹³C Breath Sample Analysis

617 Breath samples analysis was performed by isotope ratio mass spectrometry (IRMS) (Preston
618 and McMillan, 1988). Breath samples were collected by exhalation of expired breath into an
619 Exetainer (Labco Ltd, Lampeter, Ceredigion, United Kingdom) using a straw. Participants
620 were encouraged to continue to blow into the Exetainer until condensate was observed in the
621 base of the tube indicating alveolar breath collection (Edwards et al., 2002). Collected breath
622 samples were analysed by flushing a portion of breath with helium gas into the IRMS where
623 water is removed, and CO₂ separated from other gas species using gas chromatography before
624 introduction into the mass spectrometer (AP2003, GV Instruments, Manchester, UK). The
625 isotope ratio ¹³C:¹²C was calculated from the ion abundance of m/z 44, 45 and 46 with reference
626 to a laboratory reference CO₂ (itself calibrated against Vienne Pee Dee Belemnite (*VPDB*))
627 with correction of the small contribution of ¹²C¹⁶O¹⁷O at m/z 45, the Craig correction. Breath
628 □¹³C enrichment (‰) over baseline was calculated for each timepoint and the envelope of
629 breath ¹³C excretion was analysed using a modified version of the curve-fitting techniques to
630 compute gastric emptying T_{1/2} times (Ghoos et al., 1993).

631 Biological Sample Collection and Processing

632 Ten millilitres of blood were collected at each timepoint for assay of plasma glucose (EDTA),
633 serum insulin, and plasma gut hormones (3 ml in lithium heparin tube containing 60 ul
634 aprotinin protease inhibitor; Nordic Pharma UK). All blood sample tubes were centrifuged at
635 2500 X g for 10 min at 4⁰C. Samples were separated and frozen at -80⁰C until the end of the
636 study where analysis took place.

637 Biological Sample Analysis

638 Glucose analysis was performed using Randox Glucose (GLU/PAP) kit supplied by Randox
639 using 20 ul of plasma glucose. A human insulin radioimmunoassay kit (Millipore) was used
640 for analysis of insulin based on manufacturer's specification with 50 ul serum. GLP-1 was
641 measured with the use of previously established in-house specific and sensitive
642 radioimmunoassay. GIP was measured by using an ELIZA Human GIP (Millipore) based on
643 manufacturer's specification with the use of 20 ul serum sample.

644 Experiments Ex Vivo

645 FITC labelled α -amylase was added to a suspension containing pea cells. Images of the cells
646 were taken at different time points using an Olympus BX 60 Fluorescence Microscope (Figure
647 X, I and J) or a Zeiss LSM 880 Confocal Laser Scanning Microscope (Figure Y and Z).

648 Metabolomic Gastric and Duodenal Samples Analysis

649 *Samples Extraction*

650 Gastric and duodenal samples were centrifuged for 15 minutes at 3000 X g. Metabolites were
651 extracted from the gastric and duodenal samples using a modified folch extraction procedure.
652 Two millilitres of chloroform/methanol in a 2:1 ratio was added to 450 ul of each gastric and
653 duodenal sample. This mixture was vortexed and 1ml of purified water was added. Samples
654 were vortexed for 1 minute and centrifuged for another 20 min at 3000 X g, at 0° C. This
655 method produced two phases and metabolites split into the aqueous and the organic phase
656 according to their polarity. The aqueous phases were separated and evaporated to dryness using
657 a speed vacuum concentrator and the dried sample was stored at -80°C prior analysis. The NMR
658 profiles of the stomach and duodenal digested samples were analyzed by ¹H high resolution
659 NMR spectroscopy.

660 *Sample treatment*

661 The dried aqueous phase of the gastric samples was re-constituted in 540 ul of H₂O and were
662 sonicated for 20 minutes. 540 ul were mixed with 60 ul of a 3M phosphate buffer (pH 7.4, 80%
663 D₂O) containing 1 mM of the internal standard, 3-(trimethylsilyl)- [2,2,3,3, -²H₄]-propionic acid
664 (TSP) were added and the mixture was transfer to the 5mm NMR tubes. The dried aqueous
665 phase dried of the duodenal samples were re-constituted in 640 ul of H₂O and were sonicated
666 for 20 minutes. 540 ul were mixed with 60 ul of a 1.5M phosphate buffer (pH 7.4, 80% D₂O)

667 containing 1 mM of TSP were added and the mixture was transfer to the 5mm NMR tubes.
668 Quality control samples were prepared independently for gastric and duodenal samples by
669 pooling 90 ul of each sample.

670 ¹H-NMR Metabolic profiling analysis

671 ¹H-NMR spectroscopy was performed on the aqueous phase extracts at 300 K on a Bruker 600
672 MHz spectrometer (Bruker Biospin, Karlsruhe, Germany) using the following standard one-
673 dimensional pulse sequence with saturation of the water resonance RD – gz,1 – 90° – t – 90° –
674 tm – gz,2 – 90° – ACQ (noesygprr1d) where RD is the relaxation delay, where 90° represents
675 the applied 90° radio frequency (rf) pulse, t1 is an interpulse delay set to a fixed interval of 4μs,
676 RD was 2 s and tm (mixing time) was 100 ms. Water suppression was achieved through
677 irradiation on the water signal during RD and tm. For the gastric and duodenal samples, each
678 spectrum was acquired using 4 dummy scans followed by 32 scans and collected into 64K data
679 points. A spectral width of 20,000 Hz was used for all the samples. Prior to Fourier
680 transformation, the FIDs were multiplied by an exponential function corresponding to a line
681 broadening of 0.3 Hz. ¹H NMR spectra were manually corrected for phase and baseline
682 distortions and referenced to the TSP singlet at δ 0.0. Spectra were digitized using an in-house
683 MATLAB (version R2014a, The Mathworks, Inc.; Natwick, MA) script. Spectra were
684 subsequently referenced to the internal chemical shift reference (trimethylsilyl- [2,2,3,3, -²H₄]-
685 propionate, TSP) at δ 0.0. Spectral regions corresponding to the internal standard (δ -0.5 to 0.5)
686 and water (δ 4.57 to 5.18) were excluded. All spectra were normalised using median fold
687 change normalisation using the median spectrum as the reference and imported into MatLab to
688 conduct multivariable statistical analysis. Data were centred and scaled to account for the
689 repeated measures design and then modelled using partial-least-squares– discriminant analysis
690 (PLS-DA) with Monte Carlo cross-validation (MCCV). The fit and predictability of the models
691 obtained were determined and expressed as R²Y and Q²Y values, respectively.

692

693 NMR Compound Identification

694 A combination of data-driven strategies such as Statistical Total Correlation SpectroscopyY
695 (STOCSY) and SubseT Optimization by Reference Matching – (STORM) and a catalogue
696 of 1D ¹H NMR sequence with water pre-saturation and 2D NMR experiments such as *J*-
697 Resolved spectroscopy (jresgprrqf), ¹H–¹H Total Correlation SpectroscopyY (TOCSY
698 (mlevphpr.2)), ¹H–¹H COrrrelation SpectroscopyY (COSY (cosygprrqf)), ¹H–¹³C Hetero-

699 nuclear Single Quantum Coherence (HSQC (hsqcetgpsisp2.2)) and ^1H - ^{13}C Hetero-nuclear
700 Multiple-Bond Correlation (HMBC (hmbcgp1ndprqf)) spectroscopy were applied to identify
701 metabolites for the gastric and duodenal samples. Additional experiments were conducted in
702 order to acquire enhanced spectra by reducing the overlap mainly on the carbohydrate
703 resonances of the chemical shift region. The gradient-enhanced multiple-quantum-filtered
704 COSY pulse sequence (cosygpmfqr) was used to acquire both double-quantum-filtered and
705 triple-quantum-filtered COSY experiments in order to simplify cross peaks by filtering out
706 uncoupled protons and artifact peaks. ^1H - ^{13}C multiplicity-edited HSQC (hsqcedetgpprsisp2.3)
707 spectrum was also acquired to differentiate methines (-CH-) and methyls (-CH₃) from
708 methylenes (-CH₂-). 2D-NMR experiments were acquired using their corresponding pulse
709 sequences with water presaturation during relaxation delay. Selective 1D TOCSY (selmlgp)
710 experiments were also obtained.

711 Objective assessment of peas intake

712 Urine samples were collected at baseline and follow up visits of the 28 days pea
713 supplementation period. Briefly, 540 ul of urine samples were mixed with 60 ul of a pH 7.4
714 phosphate buffer containing 1 mM of the internal standard TSP as previously described. ^1H -
715 NMR spectroscopy was performed on the urine samples at 300 K on a Bruker 600 MHz
716 spectrometer (Bruker Biospin, Karlsruhe, Germany) using the following standard one-
717 dimensional pulse sequence with saturation of the water resonance RD – gz,1 – 90° – t – 90° –
718 tm – gz,2 – 90° – ACQ (noesygp1d) using an established method. ^1H NMR spectra were
719 manually corrected for phase and baseline distortions and referenced to the TSP singlet at δ
720 0.0, using an in-house MATLAB (version R2014a, The Mathworks, Inc.; Natwick, MA) script.
721 Urinary trigonelline was identified in the 1D ^1H -NMR spectra at δ 9.13(s), δ 8.84(t) and δ
722 4.44(s). Trigonelline quantification was performed as previously described (Garcia-Perez et
723 al., 2016).

724 Quantification of ^{13}C plasma glucose

725 Plasma samples were diluted 1:5 with L-fucose internal standard. The ^{13}C natural abundance
726 of L-fucose was separately calibrated against VPDB and used as a chemical and isotopic
727 internal standard. 0.5 ml of plasma was diluted with 2 ml internal standard. Samples then
728 underwent ultrafiltration using 30000 molecular weight cut-off ultrafiltration devices (Amicon
729 Ultra 4; Millipore, Watford, UK) at 3600 X g for 45 minutes to remove proteins and other high
730 molecular weight compounds. After this step, the samples were stored in two separate aliquots

731 at -20°C for further analysis. Analysis by liquid chromatography-IRMS (LC-IRMS) was
732 performed as previously described. Fucose and glucose peak areas and background-corrected
733 isotope ratios were exported to a spreadsheet for analysis. Glucose enrichment ($\delta^{13}\text{C}$ (‰)) was
734 calculated using an in-house routine using a relative ratio analysis approach against the IS for
735 each sample to report the enrichment of glucose relative to VPDB and glucose ^{13}C
736 concentration was calculated as the product of enrichment x concentration at each time point.
737 Glucose concentration was calculated from the area ratio of the glucose peak area relative to
738 fucose.

739 Quantification of ^{13}C SCFAs in urine samples

740 Samples were analysed using procedure from previously described (Morrison et al., 2004)
741 which was modified to increase sensitivity of the analysis. In brief, urine samples (7 ml) were
742 spiked with 200 nmoles 3-methyl valerate (3mV; internal standard) and 200 μL NaOH (300
743 mmoles/L). A ‘process blank’ was prepared containing freshly deionized water and identical
744 spikes of 3mV and NaOH. Samples and blanks for each run were dried on a vacuum
745 concentrator (Jouan RC10 Vacuum Centrifuge, ThermoFisher, Paisley, UK) at ambient
746 temperature. Dried samples were acidified with 100 μl HCl and SCFA extracted with 400 μl
747 methyl-tert butyl ether. 300 μl of the MTBE phase was removed to clean vials for analysis by
748 GC-C-IRMS as previously described (Morrison et al., 2004). The isotopic enrichment of each
749 SCFA was calculated relative to 3mV which itself had been calibrated against laboratory
750 standards and VPDB. Enrichment of each SCFA with time was expressed relative to the
751 enrichment of the starting pea material ingested to derive a fractional ^{13}C enrichment curve for
752 each SCFA.

753 Bacterial Composition Analysis of Stool Samples collected for study 3

754 Total DNA was extracted from stool samples (~200 mg) using the FastDNA SPIN Kit for Soil
755 (MP Biomedicals, UK) with a bead-beating step (Kellingray et al., 2017). DNA yield was
756 quantified using the Qubit fluorometer prior to the samples being sent to the Earlham Institute
757 (Lindström et al.), where the V4 hypervariable region of the 16S rRNA genes were amplified
758 using the 515F and 806R primers with built-in degeneracy (Caporaso et al., 2011). The
759 amplicons were sequenced using paired-end Illumina sequencing (2 \times 250 bp) on the MiSeq
760 platform (Illumina, USA). Sequencing data were analysed using the Quantitative Insights Into
761 Microbial Ecology (QIIME) 1.9 software and RDP classifier 16S rRNA gene sequence
762 database (Wang et al., 2007). The trimmed reads were filtered for chimeric sequences using

763 ChimeraSlayer, bacterial taxonomy assignment with a confidence value threshold of 50% was
764 performed with the RDP classifier (version 2.10), and trimmed reads clustered into operational
765 taxonomic units at 97% identity level. Weighted and unweighted UniFrac distances were used
766 to generate beta diversity principal coordinates analysis plots, which were visualised using the
767 Emperor tool.

768 Bacterial Composition Analysis of Stool Samples collected for study 4

769 Stool samples were collected at baseline and follow up at each supplementation period. The
770 samples were stored at -80°C for between 6-9 months before processing. DNA was extracted
771 from approximately 250 mg of stool samples using the PowerLyzer PowerSoil DNA Isolation
772 Kit (Mo Bio, Carlsbad, CA, USA) following manufacturer's instructions. Samples were bead
773 beaten for 3 min at speed 8 in a Bullet Blender Storm (ChemBio Ltd, St. Albans, UK) and this
774 was the only modification to the protocol. All samples were analysed in a single batch. Sample
775 libraries were prepared by amplifying the V1-V2 region of the 16S rRNA gene following
776 Illumina's 16S Metagenomic Sequencing Library Preparation Protocol with the following
777 alterations. First, the index PCR reactions were cleaned up and normalised using the
778 SequelPrep Normalization Plate Kit (Life Technologies, Paisley, UK). In addition, sample
779 libraries were quantified using the NEBNext Library Quant Kit for Illumina (New England
780 Biolabs, Hitchin, UK). Sequencing was performed on an Illumina MiSeq platform (Illumina
781 Inc., Saffron Walden, UK) using the MiSeq Reagent Kit v3 (Illumina) using paired-end 300bp
782 chemistry. The resulting sequencing data was processed following the DADA2 pipeline as
783 previously described. The SILVA bacterial database version 132 was used to classify the
784 sequence variants. The UniFrac weighted distance matrix generated from Mothur was used to
785 generate non-metric multidimensional scaling (NMDS) plots and PERMANOVA p-values
786 using the Vegan library within R (Dessau and Pipper, 2008). Due to high inter-individual
787 variability we examined the data as paired samples per volunteer. Differences in microbial
788 communities between and within groups were tested by using the Wilcoxon signed-rank test.

789 Digestion *In Vitro* - Study Design

790 Peas Preparation

791 Pea seeds were milled into a flour using an electric coffee grinder (Krups, Berkshire, UK), and
792 were passed through a 1mm test sieve (Cole-Palmer, St. Neots, UK). All chemicals, reagents
793 and enzymes were supplied by Sigma Aldrich (Dorset, UK) unless stated otherwise.

794 Approximately 5 g dried pea seeds were weighed and soaked overnight in 100 mL ultrapure
795 water at room temperature. After soaking, the water content of the peas was approximately 60
796 % for the *rr* peas and 45 % for the *RR* peas. For the flour, 1 g flour was weighed into a Pyrex
797 15 mL glass tube (screw cap with PTFE cap liner) and mixed with an excess of ultrapure water
798 (4:1). Samples were hydrated for 1 h at room temperature, then cooked for 1 h in a boiling
799 water bath, cooled to room temperature and more water was added to the viscous mixture (8:1).
800 The peas were boiled for 1 h in ultrapure water and drained, and the skins/testa were removed
801 from both uncooked and cooked peas and then they were pushed through a garlic press
802 (Lakeland, UK) with 2.5 mm diameter holes. This step attempted to mimic chewing and
803 produced chunks with particle sizes up to 2.5 mm.

804 Simulated digestion

805 Triplicate digestions of flours and pea chunks were carried out using a standardised static
806 biochemical model developed by Minekus et al (2014) (Minekus et al., 2014). However, the
807 compositions of the simulated digestion fluids were modified from the protocol described by
808 Minekus et al (2014). In all cases sodium bicarbonate and ammonium bicarbonate were directly
809 substituted with bis-tris, because bis-tris has a high buffering capacity which was particularly
810 important for maintaining pH 7.0 (approximately) in the intestinal phase in sealed tubes, where
811 regulation of pH by titration of 0.1M NaOH was not possible. The same simulated fluids were
812 used for all experiments and all enzymes were purchased from Sigma-Aldrich Company Ltd.,
813 Dorset, UK).

814 Oral phase: simulated salivary fluid (SIF) [15.1 mM KCl, 3.7 mM KH₂PO₄, 13.66 mM bis-tris,
815 0.15 mM MgCl₂(H₂O)₆, 1.5 mM CaCl₂(H₂O)₂] was added, 1:1 v/w, to the samples immediately
816 followed by human salivary amylase (product code A1031: type XIII-A lyophilised powder –
817 α-amylase from human saliva) to give a final concentration of 75 U/ mL, and was incubated
818 for 2 min at 37 °C.

819

820 Gastric phase: at 2 min, the sample was adjusted to pH 3.0 (± 0.05) using 0.1M HCl, simulated
821 gastric fluid (SGF) [6.9 mmol KCl, 0.9 mmol KH₂PO₄, 25.5 mmol bis-tris, 47.2 mmol NaCl,
822 0.1 mmol MgCl₂(H₂O)₆, 0.15 mmol CaCl₂(H₂O)₂] was added (1:1 v/v). Finally, pepsin (product
823 code P7012: pepsin from porcine gastric mucosa) was added to the digestion mixture to give a
824 final concentration of 2000 U/ mL, and the gastric phase was incubated at 37 °C in a shaking
825 incubator for 1 h. The recommended time for gastric digestion described by Minekus et al

826 (2014) is 2 h, however this time was reduced to 1 h, for these experiments, based on the lack
827 of starch degrading enzymes in the gastric phase.

828

829 Intestinal phase: immediately after completion of the gastric phase the pH was raised to 7.0 (\pm
830 0.05) using 0.1M NaOH, simulated intestinal fluid (SIF) was added [6.8 mM KCl, 0.8 mM
831 KH_2PO_4 , 85 mM bis-tris, 38.4 mM NaCl, 0.33 mM $\text{MgCl}_2(\text{H}_2\text{O})_6$, 0.6 mM $\text{CaCl}_2(\text{H}_2\text{O})_2$, and
832 10 mM bile] (1:1 v/v) and finally pancreatin (product code P7545: pancreatin from porcine
833 pancreas) was added to give a final concentration of 100 U/ mL. The intestinal phase was
834 incubated at 37 °C in a shaking incubator (170 rpm) for 2 h.

835

836 Flour was digested in an open, heated mixing vessel where samples were stirred continuously
837 (500 rpm) at 37 °C. The pH of the intestinal phase was maintained at 7.0 by KEM AT-700
838 automatic titrator (Kyoto Electronics, Leeds, UK). At the end of each phase of digestion, 0.1
839 mL samples were taken: oral phase 2 min; gastric phase 60 min, intestinal phase 120 min.

840 Pea chunks were digested in disposable centrifuge tubes (Greiner Bio-One Ltd, Stonehouse,
841 UK). The chunks were too large to aspirate and so to overcome this, one centrifuge tube
842 contained one sample for each time point. Pea chunks were digested at 37 °C in an orbital
843 shaking incubator (Sartorius, Goettingen, Germany) at 170 rpm, and sample collection times
844 were the same as for the flour.

845 Starch assay

846 Uncooked and cooked pea chunks (100 mg \pm 5 mg) were weighed into 15 mL centrifuge bottles
847 and were digested according to the protocol described in section 3.2. The liquid phase was
848 removed from the samples by centrifugation (2000 x g for 5 min) and careful aspiration by
849 pipette. Additional digested samples were homogenised at 1000 rpm, using a T25 Ultra-Turrax
850 (IKA, Oxford, England), post-intestinal digestion phase, to check that all starch in the pea
851 chunks had been accounted for by the assay. The samples were milled (in digestion fluid) until
852 no more chunks were visible, the ultra-turrax tip was washed with ultra-pure water and the
853 washings were combined with the milled sample. The sample was centrifuged at 10000 x g for
854 10 minutes and the supernatant was aspirated, very carefully, by pipette.

855 Total and resistant starch contents of undigested and digested flours, pea biscuits and pea
856 chunks were determined using assay kits purchased from Megazyme International (Co.
857 Wicklow, Ireland).

858 *Total starch* (assay procedure K-TSTA 07/11). Samples were heated in aqueous ethanol (80%
859 v/v) at 80-85 °C for 5 min, centrifuged at 1800 x g, 10 min. Supernatants were decanted, and
860 excess liquid was drained from the pellets.

861 Resistant starch (assay procedure: KRSTAR 09/14). Samples were incubated with 4.0 mL
862 pancreatic α -amylase (30 U/mL) and AMG (3 U/mL) for 16 h at 37 °C with continuous shaking
863 (200 rpm), during which time non-resistant starch was solubilised and hydrolysed to D-glucose.
864 Enzymes were halted by washing with 4.0 mL ethanol (99 % v/v), followed by centrifugation
865 at 1500 X g for 10 min. Supernatants were decanted and pellets were re-suspended in 8.0 mL
866 50 % ethanol and the centrifugation step was repeated, and followed by a final washing step.
867 Supernatants were decanted, and excess liquid was drained from the pellets.

868 All pellets were incubated in 2.0 mL 2 M KOH for 20 min on ice, neutralised in 8.0 mL 1.2 M
869 sodium acetate buffer (pH 3.8). Starch was hydrolysed to form maltodextrins by addition of
870 thermostable α -amylase to give a final content of 3.0 U/mL. The maltodextrins were further
871 hydrolysed by addition of AMG to give a final content of 3.3 U/mL, to form D-glucose.

872 Total starch and resistant starch contents were determined by incubating 0.1 mL of hydrolysed
873 samples with 3.0 mL GOPOD reagent [glucose oxidase plus peroxidase and 4-aminoantipyrine
874 in reagent buffer (4-hydroxybenzoic acid), at 50 °C for 20 min, where the D-glucose was
875 oxidised to D-gluconate, which was quantitatively measured in a colorimetric reaction. The
876 absorbance for each sample and D-glucose controls was read at 510 nm against the reagent
877 blank using UV tolerant cuvettes (Sarstedt Limited, Leicester, UK) and a Lambda UV/Vis
878 spectrophotometer (Perkin-Elmer, Buckinghamshire, UK).

879 Starch structural analysis- SEC and ^{13}C CP/MAS NMR

880 SEC analysis was conducted on debranched, purified starch samples using a Waters Advanced
881 Polymer Characterisation System as described in.

882 Solid-state ^{13}C CP/MAS NMR experiments on all pea and flour powder samples were carried
883 out on a Bruker Avance III 300 MHz spectrometer, equipped with an HXY 4-mm probe, spun
884 at a frequency of 12 kHz, at a ^{13}C frequency of 75.47 MHz, and MAS of 54.7°. Samples were
885 manually ground using a mortar and pestle and approximately 110–130 mg of each sample was
886 packed into a 4-mm cylindrical partially-stabilised zirconium oxide (PSZ) rotor with a Kel-F
887 end cap. The ^{13}C CP-MAS NMR experimental acquisition and processing parameters were
888 90° ^1H rf pulse width of 3.50 μs and 90° ^{13}C rf pulse width of 4.50 μs , contact time of 1000

889 μ s, recycle delay of 5 s, spectral width of 22.7 kHz (301.1 ppm), acquisition time of 28.16 ms,
890 time domain points (i.e. size of FID) of 1280, line broadening was set to 20, 6144 number of
891 scans and 16 dummy scans. All experiments were referenced to tetramethylsilane (Brouns et
892 al.) and hexamethylbenzene for ^1H and ^{13}C , respectively, and carried out at approximately 26
893 $^{\circ}\text{C}$.

894 Calculation of starch molecular (double helical) order was performed following the procedure
895 described by Flanagan and colleagues (2015). In brief, following obtaining of free induction
896 decay of all samples, the obtained data was Fourier transformed, phase corrected and zero-
897 filled to 4096 data points. Chemical shift vs relative intensity data was used to obtain an
898 estimation of the total crystallinity of each sample analysed using partial least squares analysis
899 against a reference set of 114 spectra of starch with known values of molecular order obtained
900 using spectral deconvolution and referenced against x-ray diffraction data.

901 Particle size

902 Pea chunk size (cooked) was determined after gastric and intestinal simulated digestion by
903 dynamic light scattering (DLS), using an LS13320 laser diffraction particle size analyser
904 (Beckman-Coulter, Buckinghamshire, UK), using starch as the optical model with PIDS
905 (Polarization Intensity Differential Scattering) obscuration $\geq 45\%$. The mean particle size
906 distribution was measured 3 times over 60 second intervals.

907 Microscopy

908 Microscopy was used to characterise the peas and flour throughout the digestion process; to
909 visualise any changes to the macro and microstructure of the foods. It was particularly
910 important to image areas of damaged tissue from the action of chewing, as these areas were
911 accessible to enzymes and therefore would be susceptible to digestion.

912 Light microscopy

913 Light microscopy was used to characterise the macro and microstructure of pea seeds and flour.
914 Uncooked flour samples were hydrated in ultrapure water 20 min before imaging; cooked and
915 digested flour samples were imaged immediately after cooking and digestion steps. Iodine
916 (0.2% iodine in 2% potassium iodide, aqueous) was used to stain starch.

917 Uncooked, cooked and digested pea chunks of approximately 1mm^3 were fixed in 2.5%
918 glutaraldehyde/2% formaldehyde in 0.1M PIPES buffer for 8 days, to improve starch

919 polymerisation, because using just 2.5% glutaraldehyde alone was not adequate for *RR* starch.
920 The pea chunks were washed 3 times in 0.1M PIPES buffer for 15 minutes each. The chunks
921 were then post-fixed in 1% osmium tetroxide (aqueous) for 2.5 hours before 3x15-minute
922 ultrapure water washes and an ethanol series dehydration (10, 20, 30, 40, 50, 60, 70, 80, 90,
923 100%) with at least 15 minutes between ethanol changes. The final ethanol change was
924 repeated twice more with 100% ethanol. The last ethanol wash was replaced with a 1:1 mix of
925 LR White medium grade resin (London Resin Company Ltd) to 100% ethanol and put on a
926 rotator for an hour. This was followed by a 2:1 and a 3:1 mix of LR White resin to 100%
927 ethanol and finally 100% resin, with at least an hour on the rotator between each change. After
928 1 hour in 100%, the resin was changed twice more with fresh 100% resin with periods of at
929 least 8 hours on the rotator between changes. Four blocks from each sample were each put into
930 BEEM capsules with fresh resin and polymerised overnight at 60°C. Semi-thin sections
931 approximately 1µm thick were cut using an ultramicrotome (Ultracut E, Reichert-Jung) with a
932 glass knife mounted with an ultrapure water-filled trough. The sections were picked up and
933 transferred onto a drop of water on a glass slide and dried in an oven at 100°C. The sections
934 were then stained with toluidine blue (1% toluidine blue in 1% sodium borate, aqueous) for
935 protein and iodine (0.2% iodine in 2% potassium iodide, aqueous) for starch for only a few
936 seconds and then rinsed with water before being dried again in the oven. The slides were then
937 ready to view under the microscope (Olympus BX60 microscope).

938

939 Scanning electron microscopy (SEM)

940 Pea chunks were fixed using a 2.5% glutaraldehyde/0.1M PIPES buffer (pH 7.4) for 5 days.
941 After washing with 0.1M PIPES buffer, the chunks were dehydrated in a series of ethanol
942 solutions (10, 20, 30, 40, 50, 60, 70, 80, 90, 3x 100%) and 3x 100% ethanol. Samples were
943 critical point dried in a Leica EM CPD300 critical point drier using liquid carbon dioxide as
944 the transition fluid and mounted onto SEM stubs with silver paint (Agar Scientific, Stansted,
945 UK). The samples were coated with gold in an Agar high resolution sputter-coater apparatus.
946 Scanning electron microscopy was carried out using a Zeiss Supra 55 VP FEG SEM, operating
947 at 3kV.

948

949 Statistical Analysis

950 Data were analysed using Graph Pad Prism (GraphPad Software, San Diego, CA, USA), IBM
951 SPSS (Statistics for Windows, Version 24, Armonk, NY, USA) or Mat lab version R2014a,

952 The Mathworks, Inc.; Natwick, MA). Data were tested for normality using Shapiro-Wilk
953 Test. Comparison of time series data was carried out by two-way analysis of variance
954 (ANOVA) with post hoc LSD Fisher correction. Comparison between groups was carried out
955 by paired Student's *t*-test. All results and graphs are expressed as mean \pm SEM. Results were
956 considered statistically significant when $p < 0.05$, two sided with the significance level
957 indicated as * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$. All data that support the findings of the study
958 have been deposited in Mendeley Database:

959 ([https://data.mendeley.com/datasets/g8cpyyyp3n/draft?a=3bd91ae0-42ba-4d55-8751-](https://data.mendeley.com/datasets/g8cpyyyp3n/draft?a=3bd91ae0-42ba-4d55-8751-d9ba0adeaade)
960 [d9ba0adeaade](https://data.mendeley.com/datasets/g8cpyyyp3n/draft?a=3bd91ae0-42ba-4d55-8751-d9ba0adeaade)).

1199 **Acknowledgements**

1200 We thank Dr Eleutheria Panteliou and Dr Lilian Mendoza for their help during nasogastric and
1201 nasoduodenal tubes insertion. We thank Alia Sukkar and Anna Cherta Murillo for their
1202 assistance in the randomized controlled trial study and Dr Georgia Franco Becker and Dr Claire
1203 Byrne for their help with the radioimmunoassays. We thank Mrs Eleanor McKay for technical
1204 assistance with the plasma ¹³C glucose and urine ¹³C SCFA assay and Mrs Sandra Small for
1205 technical assistance with the breath ¹³C and urine ¹³C SCFA assay and growth of isotope
1206 labelled pea seeds. We thank Dr Mary Parker for valuable discussions and interpretation of the
1207 microscopy images. All clinical trials were conducted at the NIHR/Wellcome Trust Imperial
1208 Clinical Research Facility.

1209 The Division of Integrative Systems Medicine and Digestive Disease at Imperial College
1210 London receives financial support from the National Institute of Health Research (NIHR)
1211 Imperial Biomedical Research Centre (BRC) based at Imperial College Healthcare NHS Trust
1212 and Imperial College London, in line with the Gut Health research theme. IGP is supported by
1213 a National Institute for Health Research (NIHR) fellowship (NIHR-CDF-2017-10-032). CD
1214 gratefully acknowledges support from the Department for Environment, Food & Rural Affairs
1215 (CH0103, CH0111, Pulse Crop Genetic Improvement Network; LK09126) and from the
1216 Biotechnology and Biological Sciences Research Council (BBSRC; BB/L025531/1,
1217 BBS/E/J/000PR9799). The authors also gratefully acknowledge the support of the BBSRC
1218 through the BBSRC Institute Strategic Programme Food Innovation and Health BB/R012512/1
1219 and its constituent project(s) BBS/E/F/000PR10343 (Theme 1, Food Innovation) and
1220 BBS/E/F/000PR10345 (Theme 2, Digestion in the Upper GI Tract). GF is an NIHR Senior
1221 Investigator. This research was funded by the Biotechnology and Biological Sciences Research
1222 Council (BBSRC, Grant Nos. BB/L025582/1, BB/L025418/1, BB/L025531/1,

1223 BB/L025566/1). Views expressed in this publication are those of the authors and not
1224 necessarily those of the NHS, NIHR, or the Department of Health.

1225

1226 **Authors contributions**

1227 GSF oversaw the design and implementation of the *in vivo* experiments. ESC designed and
1228 applied for ethics of the human studies. KP managed and performed all the experimental studies
1229 *in vivo*, samples processing and data analysis. RA and MK assisted in experimental human
1230 studies 2 and 3. Metabolomics analysis was performed by KP and IGP. Metabolite
1231 identification was performed by IGP and JISC. DJM and TP oversaw the stable isotope analysis
1232 and data analysis and labelled crop production (TP). LJS performed simulated digestions,
1233 starch analysis of pea seeds and particle size analysis of pea fragments; sample preparation and
1234 imaging using light microscopy and sample preparation for scanning electron microscopy.
1235 Preparation, sectioning and imaging of pea tissue sections was done by RS and KLC; KLC
1236 performed SEM. NP carried out simulated digestions of flours and subsequent starch analysis;
1237 diffusion experiments using fluorescence microscopy were also performed by NP. TK and YK
1238 carried out solid state NMR experiments. PJW, FW and CE oversaw the design and
1239 implementation of the digestions *in vitro* and microscopy studies. CD oversaw field trials of
1240 the variant pea lines and multiplication of their seeds, with quality testing for all experiments.
1241 KP, JAKM, RCS, and JMB performed 16S rRNA gene sequencing and data analysis. GF and
1242 KP led the initial drafts of the manuscript. All authors contributed to the final draft of the
1243 manuscript.

1244

1245 **Declaration of Interests:** None of the authors have a conflict of interest.
