\begin{abstract}
In spite of the continuous advancement in computer science and technology, the real-world engineering optimization process is still facing challenges due to the huge computational cost on simulations. To address this issue, TARBF algorithm (trust-region based adaptive radial basis function interpolation) for solving expensive constrained black-box optimization problems is proposed in this paper. The approach successfully decomposes the original optimization problem into a sequence of sub-problems approximated by radial basis functions in a series of trust regions. Then, the solution of each sub-problem becomes the starting point for the next iteration. According to the values of objective and constraint functions, an effective online normalization technique is further developed to adaptively improve the model accuracy in the trust region, where the surrogate is updated iteratively. Numerical experiments on 21 G-problems (CEC’2006) and 4 engineering problems prove that TARBF is a convergent paradigm, which can find more accurate solutions than other state-of-the-art metamodel-based algorithms within comparable computational budget. Moreover, the sophisticated trust region strategy developed in TARBF has the capability to facilitate an effective balance of exploration and exploitation for solving constrained black-box optimization problems.
\end{abstract}

1. Introduction

Physics-based simulation and optimization is absolutely imperative for the cost reduction required by smart and modern industry. In spite of continuous advancement in computer science, real-world engineering optimizations are still challeng-
ing due to the huge computational cost on simulations [1]. It is rarely practicable to utilize traditional global optimization methods, such as particle swarm optimization (PSO) [2] and genetic algorithms (GAs) [3], which require an awful lot of evaluations to seek an optimum. In addition, detailed finite element analysis model is usually a black-box, i.e., there is no explicit mathematical expressions of the design variables.

Faced with these limitations, surrogate modeling techniques that manage to imitate the behavior of high-fidelity model have won critical acclaim in recent years. Given a dataset containing vectors of design variables together with their responses, a metamodel can be built and used for further analysis. It is particularly beneficial to optimization because multiple calls for expensive functions can be replaced by calls for comparatively cheap metamodels.

Generally, methods for metamodel building include polynomial regression (PS) [4], radial basis function (RBF) [5], kriging [6], multivariate adaptive regression splines (MARS) [7], artificial neural networks (ANN) [8] and support vector regression (SVR) [9]. Comparative studies have been made over the past years. For example, Jin et al. [10] investigated and compared PS, Kriging, MARS and RBF models. The authors claimed that RBF metamodel outperforms others in most instances, especially in shortage of computational resource (sample size is small). With the increased fitting points, the performance of Kriging and MARS models will gain improvement. In addition, Kriging is sensitive to the noise but PR performs well in this situation. In a comparison with PR, Kriging, MARS and RBF metamodels, Clarke et al. [9] found that SVR has the overall performance in regard to accuracy and robustness with the manually optimized Gaussian kernel function. In contrast, Kim et al. [11] compared moving least squares method (MLS), Kriging, RBF and SVR metamodels and concluded that Kriging and MLS are able to build more accurate metamodels than RBF and SVR models. Therefore, it is impractical to draw any decisive conclusions on the superiority of any of the mentioned metamodels. The quality of a metamodel can vary considerably depending on how many design variables are involved, what types of the fitting functions are, and how well the predefined parameters are tuned.

Once the metamodel has been built, optimization methods can then be applied to seek for the optimum, which is therefore referred as metamodel-based or surrogate-assisted design optimization (MBDO) [12, 13]. MBDO has gained continuous development over the past two decades. For example, John et al. [14] proposed efficient global optimization (EGO), which employs Kriging metamodel. The optimization progress is guided by both the prediction and error estimations.
Younis et al. [15] also built Kriging metamodel for objective functions but a region reduction and elimination strategy is used to locate the global optimum. An application of RBF interpolation can be found in [16], which solved sub-problems in successive trust regions. In addition, metamodels have been widely incorporated into evolutionary algorithms [17, 18, 19] and particle swarm optimization [20, 21, 22] for solving expensive black-box problems.

Although the above-mentioned algorithms can obtain good results on black-box problem with boundary constraints, most of them have difficulty dealing with nonlinear constrained optimization problems. As stated by Haftka et al. [23] and Muller et al. [24], the state of the art about constrained optimization is less advanced. The main challenge lies in the definition of a general convergent scheme that seeks a feasible and optimized solution under a reasonable number of function evaluations. The hurdles become even more distinct as the number of constraints increases or when binary and discontinuous responses are present [25]. One common approach is to transform the constrained problem to an unconstrained problem by using a penalty function (penalizing the fitness value of infeasible solutions), as shown in [26, 27, 28]. However, the information of the individual constraint is lost and the additional penalty parameters need to be well tuned for different problems [29]. As a result, this penalty-based technique does not work well in solving complex constrained optimization problems. Recently, there are various novel techniques for tackling expensive constrained black-box optimization problems. For example, Brekelmans [30] applied linear approximation within sequential trust regions and used a filter method to select current iterates. Basudhar et al. [31] developed a constrained EGO, where SVM is applied to approximate the boundary of the feasible region and to support the expected improvement (EI). Regis [32] proposed the ConstrLMSRS that uses RBF surrogate to model objective and constraint functions separately. A feasible starting point is necessary in ConstrLMSRS because further candidate points are generated by perturbing all or a fraction of the coordinates of the current best feasible solution. In addition, Regis [33] developed another RBF-assisted algorithm named as COBRA, where a new iterate is selected according to the distance from previous points. Recently, a self-adjusted version of COBRA was proposed by Bagheri et al. [34] to avoid tuning the parameters manually. Dong [35] presented a kriging-based constrained global optimization algorithm SCGOSR with space reduction strategy. In SCGOSR, new added samples are selected from optimal solutions obtained by the multi-start solver.

However, relatively few algorithms can handle expensive constrained black-
Trust-region Based Adaptive RBF Algorithm

box optimization problem under severely limited budget. Jiao et al. [36] introduced a self-adaptive selection strategy into the evolutionary algorithm which combines feasibility with multi-objective problem techniques. 22 G-problems [37] have been tested and some of them (G05, G06, G08, G11, G12, G18) can be solved very efficiently in less than 1000 evaluations, but others require 5000-100000 evaluations to be solved. COBRA [33], ConstrLMSRS [32] and KCGO [38] can obtain feasible solutions on some G-problems within hundreds or thousands of function evaluations but are not competitive with regard to precision and optimality. Zahara and Kao [39] tested G04, G08, G12, which can be solved within 20000 evaluations. Bagheri’s SACOBRA [34] is very efficient that 11 G-problems can be solved within 500 function evaluations under a relaxed threshold.

In this paper, a novel trust-region based adaptive radial basis function algorithm (TARBF) is proposed for solving expensive constrained black-box problems especially under very limited budget. A description of the constrained black-box optimization problem is given in Section 2. Next, an overview of the TARBF framework is presented in Section 3.1. The following subsections will give details such as the novel design of experiments in Section 3.2, the adaptive online normalization strategy in Section 3.3, the metamodel building strategy using radial basis functions in Section 3.4, the moving trust region strategy in Section 3.5, and the early termination strategy in Section 3.6. In Section 4, the experimental and comparison results of TARBF on 25 benchmark problems are given and conclusions are drawn in Section 5.

2. Constrained black-box optimization (CBO) problem

The constrained black-box optimization (CBO) problem addressed in this paper can be formulated as follows:

\[
\begin{align*}
\min_{x \in Q} & \quad f(x) \\
\text{s.t.} & \quad g_j(x) \leq 0 \quad (j = 1, \ldots, m) \\
& \quad A_i \leq x_i \leq B_i \quad (i = 1, \ldots, d)
\end{align*}
\]  

where \( x \) refers to the vector of design variables; \( Q \) is the design space bounded by \( [A, B] \); \( A_i \) and \( B_i \) are the given lower and upper bounds on the design variable \( x_i \); \( d \) is the total number of the design variables; \( f(x) \) is the objective function; \( g_j(x) (j = 1, \ldots, m) \) is the constraint function and \( m \) is the total number of the constraint functions.

The main characteristic of a CBO problem is that there are no algebraic expressions of both the objective and the constraint functions. In other words, the
Trust-region Based Adaptive RBF Algorithm

\[
\begin{bmatrix}
    x_1 \\
    x_2 \\
    \vdots \\
    x_d \\
\end{bmatrix} \rightarrow \text{Black box (Simulation)} \rightarrow \begin{bmatrix}
    f \\
    g_1 \\
    \vdots \\
    g_m \\
\end{bmatrix}
\]

Figure 1: Black-box simulation

functional relationship between the design variables and the response is implicit. It is quite common in engineering when simulation models are used. As illustrated in Fig 1, a set of design variables \( x \in Q \subseteq \mathbb{R}^d \) are inputted to the black-box, e.g., a simulation tool, and a certain set of responses \( F(x) \subseteq \mathbb{R}^{m+1} \) are the outputs based on the unknown relationship between the variables and responses. In this paper, we assume the CBO problem is computationally expensive and the values \( f(x) \) and \( g_j(x) (j = 1, \ldots, m) \) for any input \( x \in [A, B] \) can be obtained without any crash on the simulator. Besides, the derivative information of any response is also unavailable or impractical to obtain.

3. Trust-region based adaptive radial basis function interpolation algorithm (TARBF)

3.1. Overview

TARBF is a trust-region based iterative method, which attempts to solve a sequence of constrained optimization sub-problems by using the radial basis function interpolation of the objective and constraint functions in a series of regions of interest (trust region). In this way, TARBF replaces the original optimization problem (Equation 1) by a succession of approximate subproblems as

\[
\begin{aligned}
    \min_{x \in Q^k} & \quad \tilde{f}^k(x) \\
    \text{s.t.} & \quad \tilde{g}_j^k(x) (j = 1, \ldots, m) \\
    \text{where} & \quad Q^k = [A^k, B^k] \subseteq \mathbb{R}^d, \\
    & \quad A^k_i \geq A_i, \ B^k_i \leq B_i (i = 1, \ldots, d)
\end{aligned}
\]  

(2)

where \( \tilde{f}^k(x) \) and \( \tilde{g}_j^k(x) (j = 1, \ldots, m) \) are approximated objective and constrained functions respectively, \( Q^k \) is the subregion in \( k_{th} \) iteration that bounded by \( A^k \) and \( B^k \). The solution of an individual sub-problem becomes the centering point of the trust region in the next iteration and the trust region is resized based on several indicators. This procedure is repeated until certain termination criteria are satisfied. In each iteration, a large portion of the fitting points are generated in the
current trust region, and the rest is taken from the pool of points in the previous iterations.

Figure 2 shows the optimization process of TARBF step by step and Figure 3 displays graphically how the trust regions are progressively resized and moved towards the optimum in a 2D optimization problem.

3.2. Design of experiments (DOE) strategies

As discussed by Kitayama [40], the key for obtaining the high-quality approximate global minimum is simultaneously adding new sampling points around (1) the optimum in the subregion and (2) the sparse region in the design space. TARBF achieves the two requirements with the novel design of experiments (DOE) and the moving trust region strategy. As metamodels are constructed within sequential trust regions centered at the successive sub-optimums, the first requirement above
is automatically achieved in TARBF. More specifically, the design of experiments (DOE) applied in TARBF to build the metamodel comprises three parts of the sampling points as shown in Figure 4. The first part of points (rectangle points in Figure 4) are randomly generated inside the trust region by the maxmin stochastic sampling strategy (MSS) [41, 42]. An additional constraint on the minimal distance between the points is imposed to improve the uniformity of the random plan. Besides, an extended-box selection strategy (EBS) is applied to select previous points located in the neighborhood of the current starting point. The size of the extended box is just 1.4 times larger than that of the current trust region and these points are considered alternatives to new points required in the current iteration. But in order to avoid the abuse of previous information which might cause the deterioration of the quality of the metamodel, only half of the number of points selected by EBS is deemed to be qualified for the alternatives. Last but not the least, for the purpose of making full use of previous information, additional points (triangle points in Figure 4) which are close to the current starting point and positioned out of the extended box are selected into the fitting pool by the global intelligence selection strategy (GIS). Summarily, MSS is responsible for uniformly scattering new points inside the trust region to improve the accuracy of the approximation. EBS is the key to maximally reducing the required number of new sampling points in each iteration without damaging the quality of the metamodel. And GIS reduces the risk
of the optimization process being trapped into local optima as a refined metamodel is built by adding points located outside of the trust region. As a result, the DOE in TARBF takes full advantage of the previous experimental data and contributes to high-accuracy local approximations. But in general, it is the trust region strategy which will be discussed in Section 3.5 that satisfies the second requirement to find the global optimum by attaining the balance between exploration and exploitation of the search space.

3.3. Adaptive normalization of the objective and constraint functions

Relatively few surrogate-based algorithms manage to scale the constraint violations to the same order of magnitude although it is a common sense that scaled constraint and objective functions can smooth the landscape of the metamodel surface and then affect the efficiency and accuracy of the optimization progress. One customary approach is to carry out a pre-process before building the metamodel. This is to say, identify the min-max range of each constraint over the entire design space and then divide each constraint by the determined values [34]. Although this technique does flatten the function by avoiding the extreme value globally, it makes the optimizer even harder to escape from the flat surface because this transformation makes the function where is already somewhat flat surface much flatter. This kind of issue also occurs in the logarithmic transformation proposed by Regis [33].
Based on the aforementioned limitations, a general, easy-to-implement and self-adaptive normalization strategy (SANS) is developed, as shown in Algorithm 1. In the first step of SANS, the maximum of actual responses (both the objective and constraint values) of the fitting points should be determined by

\[
\begin{align*}
g_{j}^{\text{max}} &= \max(|g_{j}(X^{k})|) \\
f^{\text{max}} &= \max(|f(X^{k})|)
\end{align*}
\]  

where \( X^{k} \) is the set of fitting points which are used for metamodel building in the \( k_{th} \) iteration, \( f(x) \) is the objective function and \( g_{j}(x) \) \((j = 1, \ldots, m)\) are the \( j_{th} \) constraint functions. Then, the objective and constraint functions could be normalized respectively according to

\[
\begin{align*}
g'_{j}(x) &= \frac{g_{j}(x)}{g_{j}^{\text{max}}} \cdot \delta_{g} \in [-\delta_{g}, \delta_{g}], \quad \text{if } g_{j}^{\text{max}} > \delta_{g} \\
f'(x) &= \frac{f(x)}{f^{\text{max}}} \cdot \delta_{f} \in [-\delta_{f}, \delta_{f}], \quad \text{if } f^{\text{max}} > \delta_{f}
\end{align*}
\]

where \( g'_{j}(x) \) and \( f'(x) \) are the normalized constraint and objective functions; \( \delta_{g} \) and \( \delta_{f} \) are two user-specified parameters. Note that usually the inappropriate normalization of objective function (\( \delta_{f} \) takes a relatively small value and smaller than \( \delta_{g} \)) would obscure the improvement over consecutive iterations, thus, \( \delta_{f} \) should be much larger than \( \delta_{g} \). Based on our numerous test results, \( \delta_{g} = 1.0 \) and \( \delta_{f} = 10.0 \) would be good choices for general optimization tasks.

In this way, the constraint and objective functions can be normalized adaptively during the entire optimization process. When the trust region \( Q^{k} \) is large, the responses of the points located in \( Q^{k} \) usually differ much from each other and then they will be scaled to the same level accordingly. In this situation, SANS is similar with the usual approach. However, when the trust region \( Q^{k} \) is sufficiently small, normally there will be few extreme values in objective and constraint functions in such small design space. In this situation, the conditions \( g_{j}^{\text{max}} > \delta_{g} \) and \( f^{\text{max}} > \delta_{f} \) are usually not satisfied and then there is no need to scale the functions. On the other hand, if the landscape of the function in such small region is still not flat, the SANS will be activated as normal. But since the maximum response values \( g_{j}^{\text{max}} \) and \( f^{\text{max}} \) generally should be smaller than the values in the initial stage, only a minor scale is sufficient enough to be applied to the original functions in support of accurate metamodels. Compared with the customary normalization strategy, SANS avoids the risk of normalizing the functions too much and improves the quality of approximations.
Algorithm 1: Self-adaptive normalization procedure (SANS)

**Function SANS**($\delta_f, \delta_g, f(X^k), g_j(X^k) (j = 1, \ldots, m))$:

**Input:**
- $\delta_f$: Normalizing the objective function value into the range $[-\delta_f, \delta_f]$.
- $\delta_g$: Normalizing the constraint function value into the range $[-\delta_g, \delta_g]$.
- $f(X^k)$: The objective function values of the fitting points.
- $g_j(X^k)$: The $j_{th}$ constraint function values of the fitting points.

**Output:**
- $f'(x)$: The normalized objective function
- $g_j'(x)$ ($j = 1, \ldots, m$): The normalized constraint functions

\[
\begin{align*}
&f_{\text{max}}, g_{\text{max}} = \max(|f(X^k)|, |g_j(X^k)|) \\
&\text{if } f_{\text{max}} > \delta_f \text{ then} \\
&\quad \begin{align*}
&f'(x) = \frac{f(x)}{f_{\text{max}}} \cdot \delta_f
\end{align*}\quad \triangleright \text{Objective normalization} \\
&\text{else} \\
&\quad \begin{align*}
&f'(x) = f(x)
\end{align*}
\end{align*}
\]
\[
\begin{align*}
&\text{if } g_{\text{max}} > \delta_g \text{ then} \\
&\quad \begin{align*}
&g_j'(x) = \frac{g_j(x)}{g_{\text{max}}^j} \cdot \delta_g
\end{align*}\quad \triangleright \text{Constraint normalization} \\
&\text{else} \\
&\quad \begin{align*}
&g_j'(x) = g_j(x)
\end{align*}
\end{align*}
\]

Return $f'(x), g_j(X^k) (j = 1, \ldots, m)$

3.4. Metamodel building using radial basis functions

Generally, any type of metamodel can be implemented in this trust region based framework. But by taking into account the computational time, the model accuracy and the model complexity, we use the simpler radial basis function surrogate in this paper. Given $n$ distinct points $x_1, x_2, \ldots, x_n \in \mathbb{R}^d$ and their corresponding real function values $f(x_1), f(x_2), \ldots, f(x_n)$, where $f(x)$ could be either the objective function or the constraint function. The metamodel built by radial basis function interpolation can be expressed as

\[
s(x) = \sum_{i=1}^{n} \lambda_i \phi (\| x - x_i \|) + p(x), x \in \mathbb{R}^d \tag{5}
\]

where $\| x - x_i \|$ is the Euclidean distance between the studied point $x$ and the fitting point $x_i$. The coefficient $\lambda_i$ is the unknown parameter that needed to be determined during the process of metamodel building. $P(x)$ is a linear polynomial.
in $d$ variables with $d + 1$ coefficients as in the form:

$$p(x) = c_0 + c_1 \cdot x_1 + c_2 \cdot x_2 + \ldots + c_d \cdot x_d = c^T \cdot x$$  \hspace{1cm} (6)$$

where $\phi$ is the radial basis function which can be of any forms but are always radially symmetric. Common types include the cubic ($\phi(r) = r^3$), multiquadric ($\phi(r) = -\sqrt{r^2 + \gamma^2}$), Gaussian ($\phi(r) = \exp(-\gamma r^2)$) and thin plate spline ($\phi(r) = r^2 \log r$) forms. Here, $\gamma$ is a shape parameter related to the smoothness of the function [43]. In this paper, the cubic form of RBF is adopted because it was successfully employed in several surrogate-based algorithms [44, 34, 16] and Wild et al. [45] suggested that the cubic variant is better than other choices especially under limited budget in terms of accuracy. Although the model accuracy can be improved by tuning the shape parameter $\gamma$ when Gaussian or thin plate spline form is used, the additional computational burden may be unbearable especially for large-scale optimization problems.

To determine the parameters $\lambda_i$ and $c$, it results in the following linear system of equations:

$$\begin{bmatrix} \Phi_{n \times n} & P_{n \times (d+1)}^T \\ P & 0_{(d+1) \times (d+1)} \end{bmatrix} \begin{bmatrix} \lambda_{(n)} \\ c_{(d+1)} \end{bmatrix} = \begin{bmatrix} F_{(n)} \\ 0_{(d+1)} \end{bmatrix}$$  \hspace{1cm} (7)$$

where $\Phi$ is an $n \times n$ square matrix containing evaluations of the RBF for the distances between all the sampling points, i.e., $\Phi_{ij} = \phi(\|x_i - x_j\|) (i, j = 1, \ldots, n)$. $P \in \mathbb{R}^{n \times (d+1)}$ is a matrix, of which the $i$-th row is $[1, x_i^T]$. $0_{(d+1) \times (d+1)} \in \mathbb{R}^{(d+1) \times (d+1)}$ is a zero matrix, $\lambda_{(n)} = [\lambda_1, \ldots, \lambda_n]^T \in \mathbb{R}^n$, $c_{(d+1)} = [c_0, c_1, \ldots, c_d]^T \in \mathbb{R}^{d+1}$, $F_{(n)} = [f(x_1), f(x_2), \ldots, f(x_n)]^T \in \mathbb{R}^n$ and $0_{(d+1)} \in \mathbb{R}^{d+1}$ is a vector of zeros. The coefficient matrix in Equation 7 is invertible if it has full rank. In other words, there exits a subset of $d + 1$ linearly independent points among the fitting sets.

3.5. Modified trust region strategy

Once the RBF surrogates for the objective and constraint functions have been identified, the optimization subproblem (Equation 2) can be solved using any mathematical or metaheuristic solvers. Here, the sequential quadratic programming (SQP) solver in Scipy library [46] is employed as an optimizer to find the optimal solution mathematically. Then, the new search subregion in the next iteration, which is centered at this optimal solution should be determined, i.e., the move limits $A^k_i$ and $B^k_i$ should be updated. Inspired by the move limit strategy described in [47], several indicators as shown in Table 1 have been formulated in support of moving and resizing the trust region.
Table 1
Indicators for trust region strategy

<table>
<thead>
<tr>
<th>Indicator</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>1st indicator</td>
<td>The size of the current trust region $Q^k$</td>
</tr>
<tr>
<td></td>
<td>Small</td>
</tr>
<tr>
<td>2nd indicator</td>
<td>The location of $x^{k+1}$ in local bounds $[A^k, B^k]$ and global bounds $[A_i, B_i]$</td>
</tr>
<tr>
<td></td>
<td>internal</td>
</tr>
<tr>
<td>3rd indicator</td>
<td>The movement history of each design variable $x_i^{k+1}$ ($i = 1, \ldots, d$)</td>
</tr>
<tr>
<td></td>
<td>forward</td>
</tr>
<tr>
<td>4th indicator</td>
<td>The movement history of $x^{k+1}$ in the design space</td>
</tr>
<tr>
<td></td>
<td>Forward</td>
</tr>
</tbody>
</table>

The first indicator is the size of the current search subregion $Q^k$. If $Q^k \leq \Delta_{min}$, the size of $Q^k$ will be marked as ‘Small’, or else it will be denoted as ‘Large’.

The second indicator is used to identify the location of each design variable $x_i^{k+1}$ ($i = 1, \ldots, d$) of the sub-optimal solution $x^{k+1}$ in current bounds $[A^k_i, B^k_i]$ and in global bounds $[A_i, B_i]$. If none of the current move limits $([A^k_i, B^k_i])$ is active (for example, when one design variable reaches either the upper bound or the lower bound, this move limit is activated), this variable $x_i^{k+1}$ ($i = 1, \ldots, d$) is considered an ‘internal’ variable. If any of the current move limits $([A^k_i, B^k_i])$ is active but none of the global bounds $[A_i, B_i]$ is active, the location of this variable is marked as ‘external’. Otherwise the location is denoted as ‘boundary’.

The third indicator illustrates the movement history of each design variable $x_i^{k+1}$ ($i = 1, \ldots, d$). For simplicity, a measure $\theta_i^k$ ($i = 1, \ldots, d$) is defined as

$$\theta_i^k = (x_i^{k+1} - x_i^k) \cdot (x_i^k - x_i^{k-1}) (i = 1, \ldots, d)$$ \hspace{1cm} (8)

If $\theta_i^k > 0$, the movement of this variable in this dimension is considered ‘forward’. Otherwise, this variable is moving ‘backward’.

The forth indicator aims to show the movement history of the sub-optimal solution $x^{k+1}$ in the design space. Therefore, the angle between the last two move vectors is defined as

$$\varphi^k = \frac{x^{k+1} - x^k}{|x^{k+1} - x^k|} \cdot \frac{x^k - x^{k-1}}{|x^k - x^{k-1}|}$$ \hspace{1cm} (9)

If $\varphi^k > 0.5$, the optimization process is moving more or less in the same direction, so the sub-optimal solution is moving ‘Forward’. If $\varphi^k <= 0$, the convergence
history is marked as ‘Backward’. Otherwise, the next search subregion will not be dependent on this indicator because the movement of optimal solutions is ‘Uncertain’.

Based on the above indicators, the next search subregion $Q^{k+1}$ can be determined by new move limits $A_i^{k+1}$ and $B_i^{k+1}$ as

$$B_i^{k+1} - A_i^{k+1} = \tau_i^k \cdot (B_i^k - A_i^k)$$

where $\tau_i^k$ is the resizing coefficient. In the current implementation, $\tau_i^k = 1.5$ is used for enlargement and $\tau_i^k = 1/1.5$ is used for reduction. To ensure a robust exploration of the design space, in the first $k_{RES}$ (the default value is 5) iterations, the subspace of each design variable will only be shrunk when this variable is located at either the global lower bound or the global upper bound, i.e., this variable is considered ‘boundary’. Otherwise, the size of the subspace will remain unchanged to keep the global searching ability. And in order to achieve a moderate exploitation of the promising region where the global optimum might be located, the subspace of each design variable will only be shrunk when this variable is not located on the global bounds and the movement history is labelled as ‘Backward’. A schematic description of the trust region strategy is given in Figure 5. The symbols $\parallel$ (logical OR) and $\&$ (logical AND) are logical operators. For example, only if the $i_{th}$ variable is ‘external’ and ‘forward’, the subspace will be enlarged accordingly.

3.6. Early termination strategy (ETS)

The early termination strategy (ETS) is developed to abort the optimization process appropriately if a really good solution has been found and there seems no big margin for improvement on this solution. In the current implementation, ETS will be activated if three conditions are all satisfied. First, the obtained sub-optimal solution $x^{k+1}$ in $k_{th}$ iteration should be feasible because an infeasible solution is definitely not the global optimum and indicates that the optimization process should continue to run. Second, the variation of the objective function values of the last two sub-optimal solutions defined by $I = f(x^{k+1}) - f(x^k)$ should be positive and less than a small value $I_{max}$ (for example, $1e-8$). If this condition is satisfied, the optimization process possibly converges to a solution so there will be little room for reduction on the objective function value. Third, in order to avoid premature convergence, the relative size of the current search subregion $S^k$ should be smaller than a proposed value of $\Delta_{min,2}$. From numerical tests, $\Delta_{min,2} = 0.01$ is a suitable value for solving general optimization tasks.
4. Experimental results

In this section, computational experiments are executed for the purpose of evaluating how well TARBF performs on seeking the global optima of the black-box constrained optimization problems.

4.1. Benchmark functions

In this work, 21 well-known G-problems of CEC’2006 test suite [37] are used for performance evaluation. Here we do not consider the problems G02, G20 and G22 which are hardly solved by any metamodel-based algorithms. Table 2 shows the main properties of the benchmark functions and please refer to [37] for more details about the functions. Note that in this study, all equality constraints \( h(x) = 0 \), are converted into inequality constraints of the form \( |h(x)| - \epsilon \leq 0 \) and \( \epsilon = 1e - 6 \) is used for both equality constraints and inequality constraints, which is more stringent than the proposed value \( \epsilon = 1e - 4 \) in CEC’2006. Hence, we use the results given in [48] and [49] as known optima for problems including equality constraints (G03, G05, G11, G13, G14, G15, G17, G21, G23).

* The problem in bold face means that the optimum satisfies a more stringent constraint tolerance \((1e-6)\) than the proposed value \((1e-4)\) in [37].

a The number of design variables.
b The number of inequality constraints.
c The problem contains linear (L), quadratic (Q), cubic (Q) or nonlinear (N) functions.
d The ratio between the feasible region and the entire search space.

### 4.2. Parameter settings

The parameter settings in TARBF are summarized in Table 3. Note that although there is a number of ad hoc parameters in TARBF, they have been properly adjusted and determined through extensive experiments and sensitivity analyses. The default values listed in Table 3 are configured for tackling general optimization tasks and do not need further adjustment. In this paper, TARBF is written in Python and is executed on a desktop machine with an AMD Ryzen CPU 1800X.

</tbody>
</table>

For each problem, TARBF is executed 25 times independently.

4.3. Performance criteria

To illustrate the convergence performance of TARBF, the following performance criteria are used [37].

- $x_{opt}, f(x_{opt})$: $x_{opt}$ is the best point found by TARBF and $f(x_{opt})$ is the corresponding objective value.

- Best, Worst, Average, Median: The best, worst, average and median value from all trials.

- Feasible run and feasible rate (FR): If $x_{opt}$ is feasible, this run is a feasible run and the feasible rate is equal to the number of feasible runs over total runs.

- Successful run and success rate (SR): Let $x^*$ be the known optimum of the problem, a successful run is a run which finds a feasible solution satisfying $f(x_{opt}) - f(x^*) \leq 1e - 4$. The success rate is the number of successful runs over total runs.
Trust-region Based Adaptive RBF Algorithm

- NFEs, NTEs, ANFEs, ATEs, ENFEs, EATEs, NFEs is used to record the number of function evaluations in each run when TARBF terminates and at least one feasible solution is found, while NTEs records the number of function evaluations when TARBF first finds the successful solution satisfying $f(x_{opt}) - f(x^*) \leq 1e^{-4}$. ANFEs or ATEs is the average of the values of NFEs or NTEs in all feasible runs. In addition, both ENFEs and EATEs are defined as $\text{ENFEs or EATEs} = \frac{\text{ANFEs or ATEs}}{\text{SR} \cdot \text{FR}}$. Generally, ENFEs reflects the maximum function evaluations required by TARBF to find the optimal solution with high robustness while EATEs shows the minimum function evaluations used. The difference between ENFEs and EATEs actually represents the convergence capability of TARBF. If this value is small, it means TARBF converges to the global optimum quickly, and vice versa.

4.4. General performance of TARBF

Table 7 shows the optimal objective values obtained by TARBF and Table 4 presents the convergence statistics of TARBF on solving these 21 G-problems. As can be seen from the FR values in Table 4, TARBF is able to find a feasible solution of the majority of the G-problems with a one hundred percent. G10, G15 and G21 are three exceptions but the FR values are both over 90%. And according to the SR values, 21 G-problems can be classified into five classes as shown in Table 5. 11 G-problems (G01, G03, G04, G05, G06, G07, G09, G11, G15, G16 and G23) can be robustly solved by TARBF with a success rate over 92%. And another 6 problems (G10, G14, G18, G19, G17 and G24) can still be addressed by TARBF with a high success rate over 52%. Among them, the SR values of the first four cases are over 72%. In addition, TARBF shows instability in solving four problems (G08, G13, G21 and G12), of which the SR values are below 52%. The most difficult problem to TARBF is G12, on which TARBF only has 16% chance of obtaining the global optimum. This is mainly because the feasible region of this problem consists of $9^3$ disjointed spheres [37], which makes TARBF difficult to escape from local optima.

Averagely, TARBF has 76.76% chance of finding the global optimum of one of the 21 G-problems within 374.10 function evaluations. And in terms of the ENFEs value, TARBF is believed to robustly and definitely solve one G-problem within 535.69 function evaluations.

4.5. Comparisons between TARBF and other state-of-the-art metamodel-based algorithms

As shown in Table 6, TARBF is compared with various advanced metamodel-based algorithms in order to evaluate its performance. These approaches include COBRA [33], eDIRECT-C [50], SADE-kNN [51] and SACOBOA [34]. COBRA...

[33] makes use of the radial basis function (RBF) to build surrogate models of both the objective and constraint functions and works well in solving the well-known large scale optimization problem MOPTA08 [52]. eDIRECT-C [50] adaptively select metamodel type (Kriging, RBF and polynomial) in the optimization process and then a pure greedy search is conducted to seek the solution. SADE-kNN [51] applied the k-nearest-neighbors (kNN) technique to make predictions of unknown points in a differential evolution framework. In kNN, the approximate response of a unknown solution is a weighted average of the responses of the k nearest solutions from a database. SACOBRA [34] is based on COBRA [33] but capable of efficiently solving constrained problems with no parameter tuning. As the detailed optimization results of COBRA were not reported in [33], here we would use the

† The termination criteria used in algorithms are different from each other.

results obtained by Liu et al. in [50]. It is worthwhile noting that this comparison might be unfair for TARBF as other algorithms use different termination criteria. As described in Section 3.6, TARBF will terminate when it converges to a good solution. But for COBRA and eDIRECT-C, Liu et al. applied the relative error \( E = \frac{f(x_{opt}) - f(x^*)}{f(x^*)} \) as the stopping criteria. And in SACOBRA [34], a problem

is considered to be ‘solved’ if $f(x_{opt}) - f(x^*)$ ≤ 0.05 and the SR values are not reported. And for SADE-kNN, the optimization process would stop if a solution satisfying $f(x_{opt}) - f(x^*)$ ≤ 1e − 4. Overall, except TARBF, the results of other algorithms do not show the true convergence statistics reflecting the search ability in solving these problems as the global optima are used as known conditions, which is impractical in solving real-world optimization problems. Generally, if the global optimum of a problem is used as a termination criterion, the required number of function evaluations when this criterion is satisfied is less than the true number of function evaluations when the algorithm actually converges.
Nevertheless, from the comparison results, it can be concluded that TARBF is superior to other algorithms in terms of accuracy and/or efficiency and/or robustness. More specifically, as compared to SADE-kNN which tests all these 21 problems, TARBF requires only a small fraction (about \(1/10\) to \(1/1000\)) of the number of function evaluations. Besides, SADE-kNN fails to solve 5 problems (G03, G07, G10, G14 and G19). And among the rest three algorithms, COBRA seems to have severe difficulty in finding the global optimum as only 3 (G08, G11 and G12) out of the 12 problems are successfully solved. Moreover, eDIRECT-C quickly finds the optimal solutions of the majority of the twelve problems but it fails to solve three problems including G05, G09 and G13. For the other nine problems, although the number of function evaluations reported by eDIRECT-C is less than the result of TARBF, it does not mean that eDIRECT-C is much efficient than TARBF. The main issue lies in how the eDIRECT-C defines a real convergence state. Similarly, SACOBRA terminates before the real convergence as well. It shows good search ability in solving 8 out of the 10 problems (G01 to G11) but does not work well in optimizing G09 and G10 while TARBF is able to tackle these two problems with high accuracy and robustness. Hence, TARBF can be considered the best algorithm among these well-known algorithms.

4.6. Engineering examples

To comprehensively validate the correctness of TARBF, four widely-used real-world engineering problems are tested as well, including the welded beam design (WBD), the tension/compression design (SPD), the pressure vessel design (PVD) and the speed reducer design (SRD). The mathematical formulae of these problems are provided in Appendix A. Table 9 gives the main characteristics of the four engineering problems. The parameter settings and the stopping criteria here are the same as that for solving G-problems, as summarized in Table 3. For the purpose of simplicity, similar to the literatures ([54, 50]), the design variables of integer values are regarded as continuous ones.

Table 7 gives the best-median-worst results of TARBF and Table 10 provides the main convergence statistics (the performance criteria are the same as described in Section 4.3). As Compared with other algorithms including KCGO [38], eDIRECT-C [50], COBRA [50], iDEaSm [53] and SCGOSR[35] in Table 8, the proposed TARBF achieves the highest solution accuracy with the least number of evaluations.

5. Conclusion
In this paper, a novel trust-region based adaptive radial basis function (TARBF) algorithm is proposed for solving constrained black-box problems within very limited budget. This algorithm includes the economical design of experiments, the adaptive online normalization of the functions and the sophisticated trust region strategy that helps TARBF balance the exploration and exploitation of the search space for the optimal solution with a high level of accuracy and a limited number of function evaluations. Throughout 25 benchmark examples (21 G-problems and 4 engineering problems), TARBF proves to be a convergent and efficient paradigm to find the global optimum. Only about 500 function evaluations are required by TARBF in average to robustly obtain the known optimal solution. By comparison of the published results, TARBF demonstrates the promising performance and superiority over other state-of-the-art algorithms to deal with constrained problems in terms of accuracy, efficiency and robustness. Moreover, TARBF provides a valuable insight into the development of metamodel assisted robust optimization method for solving highly multi-modal and large-scale design problems with less...
computational cost.

Compliance with ethical standards

Conflict of interests The authors declare that they have no conflict of interest.

Replication of results Main Python codes for the results presented in Tables 4 and 7 are available as supplementary material. In case of questions or difficulties, readers are welcome to contact the authors. Additionally, the authors are willing to share raw data of the resulting designs upon the request.

Appendix A

1. Welded Beam Design (WBD)

As shown in Fig. 6, the beam is welded to a rigid support and is designed for the minimum cost, considering constraints on shear stress ($\tau$), bending stress ($\sigma$), buckling load ($p_c$), and end deflection ($\delta$). The design variables comprise the thickness of the weld ($x_1$), the length of the welded joint ($x_2$), the width of the beam ($x_3$) and the thickness of the beam ($x_4$). The problem can be formulated mathematically as Equation 11.
min \( f(x) = 1.10471x_1^2 + 0.04811x_3x_4(14 + x_2) \) 

s.t. \( g_1(x) = t(x) - t_{\text{max}} \leq 0 \)
\( g_2(x) = \sigma(x) - \sigma_{\text{max}} \leq 0 \)
\( g_3(x) = x_1 - x_4 \leq 0 \)
\( g_4(x) = (0.10471x_1^2 + 0.04811x_3x_4(14 + x_2)) - 5 \leq 0 \)
\( g_5(x) = 0.125 - x_1 \leq 0 \)
\( g_6(x) = v(x) - v_{\text{max}} \leq 0 \)
\( g_7(x) = p - p_c(x) \leq 0 \)

where
\( P = 6000 \text{ lb}, \quad L = 14 \text{ in}, \quad E = 30 \times 10^6 \text{ psi}, \quad G = 12 \times 10^6 \text{ psi}, \quad \tau_{\text{max}} = 13600 \text{ psi}, \quad \sigma_{\text{max}} = 30000 \text{ psi}, \quad \delta_{\text{max}} = 0.25 \text{ in} \)
\( \tau = \frac{P}{\sqrt{2x_1x_2}}, \quad \sigma = \frac{3M}{2J}, \quad M = P \left( L + \frac{x_1}{2} \right) \)
\( R = \left( \frac{x_1^2}{4} + \frac{(x_1 + x_3)^2}{2} \right)^{1/2} \)
\( \tau(x) = \sqrt{(\tau)^2 + 2\tau \cdot \frac{x_2 \cdot \sigma}{2J} + (\tau)^2} \)
\( J = 2 \left\{ \sqrt{2x_1x_2} \left( \frac{x_1^2}{12} + \left( \frac{x_1 + x_3}{2} \right)^2 \right) \right\} \)
\( \sigma(x) = \frac{6PL}{x_1x_4}, \quad \delta(x) = \frac{4PL^3}{Ex_1x_4} \)
\( P_c(x) = \frac{4.013E}{L^2} \left( 1 - \frac{x_3}{\sqrt{4x_4}} \right) \)
\( 0.1 \leq x_1 \leq 2, \quad 0.1 \leq x_2 \leq 10, \quad 0.1 \leq x_3 \leq 10, \quad 0.1 \leq x_4 \leq 2 \)

2. Tension/compression spring design (SPD)

As shown in Figure 7, the design variables include the wire diameter \( d(x_1) \), the mean coil diameter \( D(x_2) \), and the number of active coils \( N(x_3) \). The design objective is to minimize the weight of the spring subject to constraints on the minimum deflection \( g_1 \), shear stress \( g_2 \), surge frequency \( g_3 \) and the limits on the outside diameter \( g_4 \). The mathematical description of this problem is given as follows:
min \( f(x) = x_1^2x_2 (x_3 + 2) \)

s.t. \( g_1(x) = 1 - \frac{x_1^2x_3}{71785x_1^2} \leq 0 \)

\( g_2(x) = \frac{4x_2^2 - x_2x_1}{12566 (x_2x_1^2 - x_1^2)} + \frac{1}{5108x_1^2} - 1 \leq 0 \)

\( g_3(x) = 1 - \frac{140.45x_1}{x_2x_3} \leq 0 \)

\( g_4(x) = \frac{x_2 + x_1}{1.5} - 1 \leq 0 \)

where \( 0.05 \leq x_1 \leq 1; 0.25 \leq x_2 \leq 1.3; 2 \leq x_3 \leq 15. \)

3. **Pressure vessel design (PVD)**

Figure 8 shows a cylindrical pressure vessel capped at both ends by hemispherical heads. According to the American society of mechanical engineers (ASME) boiler and pressure vessel code, this vessel is designed for a working pressure of 3000 psi and a minimum volume of 750 ft\(^3\). The objective is to minimize the total cost which involves a welding cost, a material cost and a forming cost. The variables include the thickness of shell \((x_1)\), the thickness of the head \((x_2)\), the inner radius \((x_3)\), and the length of the cylindrical section of the vessel \((x_4)\). Among them, \(x_3\) and \(x_4\) are continuous variables but the thickness \(x_1\) and \(x_2\) can only take integer multiples of 0.0625 inch. The mathematical expression of this problem is given in Equation 8.

\[
\begin{align*}
\text{min} & \quad f(x) = 0.6224x_1x_2x_3 + 1.7781x_1x_3^2 + 3.1661x_2^2x_3 + 19.84x_1x_2^2x_3 \\
\text{s.t.} & \quad g_1(x) = x_1 - 0.0193x_3 \leq 0 \\
& \quad g_2(x) = -x_2 + 0.00954x_3 \leq 0 \\
& \quad g_3(x) = -x_3x_2^2 - \frac{4}{3}x_1x_2^3 + 129600 \leq 0 \\
& \quad g_4(x) = x_4 - 240 \leq 0 \\
\text{where} & \quad 1 \times 0.0625 \leq x_1, x_3 \leq 99 \times 0.0625 \\
& \quad 10.0 \leq x_2, x_4 \leq 200.0
\end{align*}
\]

4. **Speed reducer design (SRD)**

A speed reducer as shown in Figure 9 is part of the gear box of mechanical system. The total weight of the speed reducer is to be minimized subject to the nine constraints which include the limits on the bending stress of the gear teeth, surface stress, transverse deflections of the shafts and stresses in the shafts. The design variables are the face width \((x_1)\), the module of the teeth \((x_2)\),
Figure 9: Schematic view of the speed reducer

the number of teeth on pinion \((x_3)\), the length of the first shaft between bearings \((x_4)\), the length of the second shaft between bearings \((x_5)\), the diameter of the first and the second shaft \((x_6 \text{ and } x_7)\). Among them, \(x_3\) is integer and the rest are continuous. The mathematical formulation can be summarized in Equation 14.

\[
\min f(x) = 0.7854x_1x_2^2(3.333x_2^2 + 14.9334x_1 - 43.0934) \\
- 1.508x_1(x_2^2 + x_3^2) + 7.4777(x_5^2 + x_5^2) \\
