Abstract

It is challenging to develop highly-efficient and stable multifunctional electrocatalysts for improving hydrogen evolution reaction (HER), oxygen evolution reaction (OER), and oxygen reduction reaction (ORR) for sustainable energy conversion and storage systems such as water-alkali-electrolysers (WAEs) and hybrid sodium-air batteries (HSABs). In this work, high monodisperse sub-nm Pt clusters (NCs) on defective NiFe layered double hydroxides nanosheets (Ni₅Fe LDHs) are synthesized by a facile electrodeposition method. Due to the synergistic effect between homogeneous Pt NCs and abundant atomic M(II) defects, along with hierarchical porous nanostructures, the Pt/NiₓFe LDHs catalysts exhibit superior trifunctional electrocatalytic activity and durability toward HER/OER/ORR. A WAE fabricated with Pt/NiₓFe LDHs electrodes needs 1.47 V to reach a current density of 10 mA cm⁻², much lower than that of the mixed 20% Pt/C and 20% Ir/C catalysts. An HSAB assembled by Pt/NiₓFe LDHs as a binder-free air cathode displays high open-circuit voltage, narrow overpotential gap, and remarkable rechargeability. This work provides a feasible strategy for constructing free-standing efficient trifunctional electrocatalysts for sustainable energy conversion and storage systems.

Keywords

sub-nm Pt, layered double hydroxide, cation vacancies, water splitting, hybrid Na-air Battery
1. INTRODUCTION

The advancements of green and sustainable energy conversion and storage devices, such as metal-air batteries, water-alkali-electrolyzers (WAEs), and fuel cells, are crucial for addressing issues of the energy crisis, environmental pollution, and greenhouse emissions.\textsuperscript{1-3} The intrinsic sluggish kinetics and large overpotential of the half-reactions, including hydrogen evolution reaction (HER) and oxygen evolution reaction (OER) for water splitting systems, OER and oxygen reduction reaction (ORR) for metal-air batteries, greatly reduce the energy efficiency and hamper their large-scale industrialization.\textsuperscript{4, 5} Currently, noble metal-based catalysts are recognized as state-of-the-art catalysts for these reactions.\textsuperscript{6} However, Pt/C is the best known HER and ORR electrocatalyst, but a poor OER catalyst. Similarly, Ir/C and RuO\textsubscript{2} possess excellent catalytic activity for OER but not for HER/ORR.\textsuperscript{7} Therefore, it is highly desirable to develop high performance and multifunctional electrocatalysts for WAEs and metal-air batteries.

Previous studies have revealed that NiFe layered double hydroxides (NiFe LDHs) exhibit impressive OER activities in alkaline conditions due to their unique layered structure with large surface areas, which could provide abundant active sites with tunable adsorption strength of intermediates during OER.\textsuperscript{8-10} Nevertheless, the performance of NiFe LDHs is still far from satisfactory because of their poor electrical conductivity and sluggish HER/ORR electrocatalytic kinetics.\textsuperscript{10} Recent evidence suggests that the generation of cation vacancies into NiFe LDHs nanosheets is an effective route to optimize surface electronic and chemical features, improving their electronic conductivity and electrocatalytic activity.\textsuperscript{11, 12} Platinum (Pt) is generally considered as the unrivaled electrocatalyst for HER, but the catalytic activity in the alkaline environment is about two orders of magnitude lower than that in acidic electrolytes.\textsuperscript{13, 14} Pioneering works have proved that the integration of Pt into metal hydroxides is a plausible way to enhance the HER activity of Pt in basic media.\textsuperscript{14} Among various transition metal hydroxides, NiFe LDHs exhibit considerable potential as supports to immobilize Pt due to the strong synergetic interactions between Pt and site-specific supports.\textsuperscript{8, 15-17} Notwithstanding the superior properties of Pt-based catalysts, the high cost, scarcity, and poor durability significantly limit their universal application.\textsuperscript{7} Therefore, how to reduce the material cost while maintaining high catalytic performance has been a hot research topic in recent decades.\textsuperscript{18} One economical strategy is alloyed Pt with transition metals catalysts, thus the electrocatalytic performance can be enhanced through the ensemble and ligand effects.\textsuperscript{18} For example, our team has successfully fabricated PtNi bimetallic structure on NiFe LDH surface by a multi-step method, which displaying excellent bifunctional catalytic activity toward OER/ORR in basic conditions.\textsuperscript{17} It was widely accepted that Ni atoms are easily
corroded in the electrocatalytic ORR reaction, hence the alloy structure cannot maintain good durability in the long-term hybrid sodium-air battery (HSAB) rechargeability testing.\textsuperscript{17, 18} Another effective approach is to increase the atom utilization efficiency by reducing the particle size, thereby providing more active sites and improving specific activity.\textsuperscript{19} Unfortunately, Pt nanoparticles tend to spontaneously agglomerate and coagulate caused by their high surface energy, some capping/stabilizing agents including organic ligands, polymers, and surfactants are usually utilized to prevent the aggregation.\textsuperscript{20} However, the presence of capping agents on Pt nanoparticles surface inevitably limits the accessibility of active sites and decreases their catalytic activity toward HER. Moreover, the addition of the capping agent also requires complicated and energy-consuming procedures.\textsuperscript{21} Thus, a feasible strategy needs to be developed to control the growth of Pt NCs on NiFe LDHs surfaces without the use of any capping agent, while retaining the high electrocatalytic activity for HER/OER. That is challenging.

Herein, a facile electrochemical deposition strategy with subsequent strong basic etching processes was proposed to prepare uniform ultrafine sub-nm Pt clusters anchored on defect-rich NiFe LDHs (Pt/Ni\textsubscript{x}Fe LDHs) \textit{in-situ} grew on three-dimension (3D) Ni foam support. The self-standing designed structure for Pt/Ni\textsubscript{x}Fe LDHs electrodes demonstrated remarkable catalytic activity and stability towards HER/OER/ORR in alkaline media. The density functional theory (DFT) calculations showed that the introduction of base-soluble Zn(II) vacancies efficiently alters the surface electronic structure around the active sites and facilitates the adsorption of HER and OER processes intermediates. A WAE fabricated with binder-free Pt/Ni\textsubscript{x}Fe LDHs electrodes displays lower overpotentials than that of the mixed noble-metal benchmark catalysts. The binder-free Pt/Ni\textsubscript{x}Fe LDHs electrode also shows high ORR activity with a high half-wave potential. Besides, an HSAB assembled using the Pt/Ni\textsubscript{x}Fe LDHs as a binder-free cathode electrode delivers high open voltage, high round trip efficiency, and remarkable cycling durability. This study proposes a feasible and easy extendable electrochemical deposition strategy to prepare binder-free, high-performance electrodes for sustainable energy conversion and storage applications, providing new solutions to address many of the major energy and environmental challenges in other fields.

\textbf{2. RESULTS AND DISCUSSION}

\textit{2.1. Characterizations of Pt/Ni\textsubscript{x}Fe LDHs catalyst.}

The fabrication process of the Pt/Ni\textsubscript{x}Fe LDHs catalyst was schematically illustrated in Figure 1a, where the 3D Ni foam substrate (Figure S1a and b) was
immersed into the electrolyte containing Ni, Fe, Zn, and Pt precursor. Briefly, Pt/NiZnFe LDHs were electrodeposited on the surface of Ni foam under a constant potential at room temperature. Then, the as-synthesized Pt/NiZnFe LDHs were selectively etched of basic-soluble Zn elements by strong alkaline solution treatment to manufacture M(II) vacancies, leading to form ultrafine Pt NCs decorated on defect-rich NiFe LDHs nanosheets (Pt/Ni\textsubscript{x}Fe LDHs).

![Schematic illustration of the formation of Pt/Ni\textsubscript{x}Fe LDHs.](image)

**Figure 1.** (a) Schematic illustration of the formation of Pt/Ni\textsubscript{x}Fe LDHs. (b, c) SEM images of Pt/Ni\textsubscript{x}Fe LDHs obtained at different magnifications. (d) XRD patterns of Pt/Ni\textsubscript{x}Fe LDHs, Pt/NiFe LDHs, and NiFe LDHs (The peaks marked “♦” stand for the Ni foam substrate.)

Scanning electron microscopy (SEM) images at different magnifications (Figure 1b, c), showed that Pt/Ni\textsubscript{x}Fe LDHs nanosheets were assembled vertically on the entire Ni skeletons, with a lateral dimension of 50 to 200 nm and thicknesses of around 10 nm. The electrodeposited Pt/Ni\textsubscript{x}Fe LDHs displayed a hierarchical porous structure with interconnected nanosheets, thus providing plenty of exposed active sites and enhancing the diffusion of ions and the generated gas. The morphology of Pt NCs was not observed due to the small particle size, which would be characterized by transmission electron microscopy (TEM) in the following section. By tuning the composite of the metal precursor, the NiFe LDHs and Pt/NiFe LDHs were also obtained with similar nanosheets morphology and orientation (Figure S1c-f). Intriguingly, we found that the shape of basic-treated Pt/Ni\textsubscript{x}Fe LDHs nanosheets became clearer and thinner than
Pt/NiZnFe LDHs (Figure S1g, h), which can be explained by the dissolution of Zn sites accompanied by the removal of OH groups, the defective laminates tended to be more positively charged leading increased intercalated anions (CO$_3^{2-}$) to enter the interlaminar, thus reducing the interlaminar distance.$^{22}$ Figure 1d gave the X-ray diffraction (XRD) patterns of Pt/Ni$_{x}$Fe LDHs, Pt/NiFe LDHs, NiFe LDHs samples on the Ni foam. Five characteristic XRD peaks centred at 40.0°, 46.4°, 67.5°, 80.2° and 85.7° which can be assigned to (111), (200), (220), (311), and (222) diffractions of the face-centered cubic (fcc) Pt crystal structure (JCPDS 04-0802), respectively,$^{23}$ whereas the diffraction peaks for NiFe LDHs were not detected due to their amorphous feature.$^{24,25}$ Moreover, the XRD of Pt/Ni$_{x}$Fe LDHs after strong alkali etching could well keep the host structure of NiFe LDHs.

High angle annular dark-field scanning transmission electron microscopy (HAADF-STEM) images revealed that the wrinkled and ultrathin feature structure of as-synthesized Pt/Ni$_{x}$Fe LDHs nanosheets (Figure 2a, b). High magnification HAADF-STEM and TEM images indicated that uniformly dispersed ultrafine Pt NCs on defect-rich NiFe LDHs nanosheets surface with a narrow particle-size distribution (Figure 2c-f). Notably, TEM images showed that nanosheets treated with strong alkaline had a negligible change in the size distribution of Pt NCs except for the thinner nanosheets structure, compared to the pristine Pt/NiZnFe LDHs (Figure S2a-c). Surprisingly, the etched Pt/Ni$_{x}$Fe LDHs displayed a hierarchically micro-mesoporous structure, which not only facilitated diffusion of reactants but also increased the density of active sites with high accessibility. Previous research found that the atomic-scale distribution of Fe$^{3+}$ cations in NiFe-LDH nanosheets played a key role in immobilizing the [PtCl$_6^{2-}$] ions at via Fe$^{3+}$-O(H)-Pt bonds, then formed sub-2 nm Pt NCs in-situ by the following electrochemical reduction in the absence of capping reagents.$^{8,16}$ The high-resolution TEM (HRTEM) illustrated that lattice fringes were coherently extended the entire nanoparticle, confirmed the formation of a single-crystal structure (Figure 2e), which was consistent with the selected area electron diffraction (SAED) pattern (inset of Figure 2c). The lattice spacing of 0.226 nm corresponded to the (111) planes of fcc Pt,$^{20}$ which was consistent with the XRD investigation. The HAADF-STEM image and the corresponding EDS mappings were shown that the homogenous distribution of Ni, Fe, Pt, and O elements throughout the whole structure (Figure S2d). The inductively coupled plasma-mass spectrometry (ICP-MS) analysis manifested the loading amount of Pt in the optimized Pt/Ni$_{x}$Fe LDHs was 2.24 wt% (Table S1). Furthermore, XPS quantitative analysis (Table S2) displayed that the surface atomic concentration of Pt in Pt/Ni$_{x}$Fe LDHs approximately to 0.38 at%. Compared to the pristine NiFe LDHs, the decrease of surface oxygen atom content in Pt/Ni$_{x}$Fe LDHs matrix ascribed to the removal of OH groups coordinated with Zn(OH)$_x$ sites during the basic etching.
process. These results fully confirmed the successful deposition of Pt on Ni$_x$Fe LDHs nanosheets.

**Figure 2.** (a-c) HAADF-STEM, (d) TEM, (e) HRTEM images, (f) particle size distribution of deposited Pt NCs of Pt/Ni$_x$Fe LDHs. The inset in (c) displays the corresponding SAED pattern.

The formation process of Pt/Ni$_x$Fe LDHs nanosheets was further studied by controlling the deposition time. Irregularly bumped nanoparticles were observed on the surface of Ni foam in the early electrosynthesis process (100s, Figure S3a). With a prolonged time of 200s, the bumped subunits were grown bigger and denser, initially forming porous nanosheet-like structures (Figure S3b). As the electrodeposition increased to 300s, the hierarchical porous of LDHs nanosheets uniformly and densely coated the Ni foam skeleton (Figure S3c). While the LDHs nanosheets became larger and Pt NCs on the surface began aggregating with the extension of the reaction time (Figure S3D, e). Moreover, Pt/Ni$_x$Fe LDHs obtained with different electrodeposition temperatures, potential, and basic-treated time were also explored. When the deposition temperature was reduced to 0°C, the reduction metal precursor and growth rate of crystal became slow, and only small nanosheets were obtained (Figure S3f). Besides, the deposition potential was a key factor affecting the final morphology of products. The good interleaved nanosheets appeared as the deposition potential increased to -1.0 V, while became accumulation and even compaction with the continued increase of the deposition potential (Figure S4). We also investigated the effect of alkali treatment time on Pt/Ni$_x$Fe LDHs, it can be seen that the nanosheets became thinner due to the removal.
of Zn(OH)$_x$-sites, and the layered structure remained unchanged after 2.5 h (Figure S5)$^{22}$. In the present synthetic system, the morphology and contents of Pt NCs in Pt/Ni$_x$Fe LDHs could be selectively synthesized by controlling the addition of the Pt precursor in the initial electrolyte. TEM images in Figure S6a revealed that few sparse nanoparticles were formed when reduced Pt precursor contents. While the uniform distribution of Pt NCs was obtained and began to aggregate with the increasing of precursor content (Figure S6b, c). The corresponding ICP-MS results showed that with the contents of Pt precursor increasing from 1.0 to 2.0 and 3.0 mM, the deposition amount of Pt gradually increased from 1.27 to 2.24 and 3.85 wt% (Table S1). Such facile control of the morphology and loading density of Pt NCs on Ni$_x$Fe LDHs was quite important for tuning their electrocatalytic properties.

![Figure 3](image-url)

**Figure 3.** High resolution XPS spectra (a) Ni 2p, (b) Fe 2p and (c) Pt 4f in Pt/Ni$_x$Fe LDHs, Pt/NiZnFe LDHs and Pt/NiFe LDHs.

X-ray photoelectron spectroscopy (XPS) was further employed to identify the chemical environment difference of the catalysts. All the XPS spectrums revealed the presence of Ni, Fe, and Pt in the as-prepared samples, while the significantly reduced of Zn 2p peaks in the defective Pt/Ni$_x$Fe LDHs and Ni$_x$Fe LDHs further confirmed the selective etching of Zn elements by the strong basic solution (Figure S7a and S8a). Theoretically, the surrounding unsaturated metal sites can be exposed by the basic leaching of Zn(OH)$_x$ octahedrons from the LDHs matrix, leading to form Ni-O-Ni
defects, which were schematically shown in Figure 1a. Therefore, the valence states of the metal sites surrounding the atomic defects would be changed to balance the charge. As shown in Figure 3a and S8b, the Ni 2p signals of the Pt/NiFe LDHs and NiFe LDHs were negatively shift compared with pristine Pt/NiFe LDHs and NiFe LDHs, evidenced the valence states change of Ni elements. It was well accepted that the Ni 2p region can be deconvoluted into Ni$^{2+}$ and Ni$^{3+}$ coordinated to OH located at low binding energies, and their corresponding satellite peaks in the high binding energies. According to the previously reported results, the high-resolution Ni 2p spectrum for Pt/Ni$_x$Fe LDHs and Ni$_x$Fe LDHs displayed a strong Ni$^{3+}$ ions signal with a percentage of 37.1% and 37.2%, higher than those of Pt/NiFe LDHs (17.92%) and NiFe LDHs (19.7%), respectively, indicating the formation of Ni$^{2+}$ defects on the surface of Pt/Ni$_x$Fe LDHs and Ni$_x$Fe LDHs. The appeared Ni$^{2+}$ defects favoured to change the local chemical coordination and the surface electronic structure, finally promoted the chemical valences increasing from Ni$^{2+}$ to Ni$^{3+}$. The following DFT calculations proved that the introduction of cation vacancies in the LDHs surface can facilitate electron transfer and strengthen the absorption of HER and OER intermediates, thus further enhancing the electrocatalytic activity in the water-splitting process. These findings also resonated well with the previously reported studies. No obvious changes of Fe 2p spectra were observed in the as-prepared samples (Figure 3b and S8c), suggesting that the valence state of Fe kept unchanged after the basic dissolving of Zn sites. Two dominant peaks at around 712 and 725 eV belonged to Fe 2p$_{3/2}$ and Fe 2p$_{1/2}$ peaks, respectively, which were in agreement with the presence of Fe$^{3+}$ in LDHs materials. The Pt 4f spectrum in Figure 3c was divided into asymmetric doublet peaks located at 71.06 and 74.42 eV could be assigned to the Pt4f$_{7/2}$ and Pt 4f$_{5/2}$ binding energies of Pt$^0$, respectively, indicating the dominance of zero-valent Pt in the obtained Pt/Ni$_x$Fe LDHs sample, which was coincided with the HRTEM observation. The O 1s spectrum in the electrocatalysts can be decomposed into three different oxygen environments peaks, including M-O bonds, M(II)-OH and M(II)-OH functionalities (Figure S7b, S8d), respectively, which was consistent well with the earlier reported LDHs materials. The negative shift of O1s spectra in the defective Pt/Ni$_x$Fe LDHs and Ni$_x$Fe LDHs further identifying the electronic structure disturbed around the atomic defects (Ni-O-Ni). Figure S7c offered the Raman spectra of Pt/Ni$_x$Fe LDHs, the peaks at 478.1 cm$^{-1}$ and 547.8 cm$^{-1}$ were attributed to M-O-M and M-O (M=Ni$^{2+}$, Fe$^{3+}$) vibrations, respectively, while the broad peak appeared at 685 cm$^{-1}$ corresponded to the intercalated CO$_3^{2-}$, further confirmed the incorporation of LDHs matrix into the nano framework.
2.2. HER, OER and WAEs performance.

Figure 4. Polarization curves and the corresponding Tafel plots for (a, b) HER and (c, d) OER of Pt/Ni<sub>x</sub>Fe LDHs, Pt/NiFe LDHs, Ni<sub>x</sub>Fe LDHs, NiFe LDHs, commercial 20% Pt/C, RuO<sub>2</sub> and 20% Ir/C catalysts in 1M KOH solution.

The electrocatalytic performance toward HER and OER in 1 M KOH electrolyte was evaluated using a typical three-electrode configuration, and the as-prepared samples coated Ni foam was directly used as the working electrode. As shown in Figure 4a and S9a, the linear sweep voltammetry (LSV) curves for HER on Pt/Ni<sub>x</sub>Fe LDHs electrode exhibited significantly lower overpotential at different current densities, compared to that of bare Ni foam, NiFe LDHs, Ni<sub>x</sub>Fe LDHs, Pt/NiFe LDHs and commercial 20% Pt/C. The corresponding Tafel slopes of Pt/Ni<sub>x</sub>Fe LDHs (81.7 mV dec<sup>-1</sup>) was plotted in Figure 4b, smaller than Ni foam (133.1 mV dec<sup>-1</sup>), NiFe LDHs (145.7 mV dec<sup>-1</sup>), Ni<sub>x</sub>Fe LDHs (132.3 mV dec<sup>-1</sup>), Pt/NiFe LDHs (95.7 mV dec<sup>-1</sup>) and commercial 20% Pt/C (207.6 mV dec<sup>-1</sup>). Based on the former researches, the calculated Tafel slope value of the Pt/Ni<sub>x</sub>Fe LDHs catalyst indicated that the HER process follows the Volmer-Heyrovsky mechanism, where electrochemical desorption of H intermediates adsorbed (H<sub>ad</sub>) was regarded as the rate-limiting step. These results suggested that the decoration of Pt NCs efficiently improved the electrocatalytic HER activities of NiFe LDHs in alkaline media, and the induction of atomic M(II) vacancies accelerated the reaction kinetics. The superior catalytic HER performance of Pt/Ni<sub>x</sub>Fe
LDHs compared favourably with recently reported LDHs-based electrocatalysts (Table S3, Supporting Information). In addition, the stability of Pt/Ni$_x$Fe LDHs catalyst was further explored. The LSV curves were almost unchanged after 5000 consecutive cyclic voltammograms (CV) cycles (Figure S9b) and the current density of Pt/Ni$_x$Fe LDHs remained nearly stable during the long-term testing. The above findings demonstrated that the high catalytic activity, excellent durability, and mechanical robustness of Pt/Ni$_x$Fe LDHs electrode for HER.

The catalytic activities of different catalysts for OER in the same electrolyte were also assessed. As displayed in Figure 4c, the LSV catalytic current density of Pt/Ni$_x$Fe LDHs electrodes was significantly enhanced, exceeding that of Pt/NiFe LDHs, Ni$_x$Fe LDHs, Ni foam, benchmark RuO$_2$, and 20% Ir/C electrodes. Meanwhile, the Pt/Ni$_x$Fe LDHs electrodes also delivered the significantly smaller Tafel slope of 36.3 mV dec$^{-1}$ (Figure 4d), as well as the lowest overpotential under different current densities (Figure S9c). The enhanced OER performance might be ascribed to the synergic effects between M(II) defects with anchored Pt NCs on the NiFe LDHs surface. By alkaline etching of Zn in Pt/NiZnFe LDHs nanosheets, the surface electronic configuration of Ni$^{2+}$ ($t_{2g}^6e_g^0$) became adjusted and redistributed, leading form more Ni$^{3+}$ with an optimal orbital distribution ($t_{2g}^6e_g^1$). The filling of $e_g$ orbital increased the covalency of transition metal-oxygen bonds and promoted the absorption of oxygen reaction intermediates via stronger $\sigma$-bonding orbital overlap, and thus facilitated electron transfer and strengthen the absorption of OER intermediates (*O), further enhancing the electrocatalytic activity for OER.$^{12,31}$ The high electrocatalytic activity was superior to the recently reported transition metal oxides-based catalyst (Table S3). Moreover, the stability of the Pt/Ni$_x$Fe LDHs catalyst was investigated by multi-step chronopotentiometric responses. As shown in Figure S9d, with the current density increased from 10 to 200 mA cm$^{-2}$, the polarization potential increased immediately and then levels off to remain constant for the rest 3600 s for each step. Unexpectedly, the lower potential value (1.50 vs. 1.51 V$_{\text{initial}}$) was established at the same current density during the reverse process, which might be attributed to the residual trace Zn in the nanocomposites dissolved by long-term immersion of basic electrolyte, the ICP-MS results showed the weight percentage of Zn decreased from 0.64% to 0.21%, hence deriving more Ni$^{3+}$ active sites to absorb O* and decreasing the OER electrocatalytic overpotential.$^{27}$

To understand the extraordinary performance for both OER and HER, the electrochemical active surface areas (ECSA) of Pt/Ni$_x$Fe LDHs, Pt/NiFe LDHs Ni$_x$Fe LDHs, and NiFe LDHs electrode were estimated by measuring their double-layer capacitances ($C_{\text{dl}}$) using cyclic voltammetry in the non-Faradaic region. (Figure S10).$^{15}$ The calculated ECSA value of Pt/Ni$_x$Fe LDHs electrode was 364.7 cm$^{-2}$, markedly
higher than those of Pt/NiFe LDHs (280.4 cm$^{-2}$), Ni$_x$Fe LDHs (133.7 cm$^{-2}$), and NiFe LDHs (54.3 cm$^{-2}$), signifying the generation of M(II) atomic vacancies provides abundant active sites that are beneficial to the enhancement of electrocatalytic activity. Furthermore, the intrinsic catalytic activity toward HER and ORR was evaluated by calculating the TOF values.\textsuperscript{4} Obviously, Pt/Ni$_x$Fe LDHs electrode presented consistently higher TOF values over Pt/NiFe LDHs, Ni$_x$Fe LDHs, and NiFe LDHs electrodes for HER and OER, respectively (Figure S11). This striking increase of TOF highlighted its bifunctional electrocatalytic promising for high-performance water splitting systems. The electrochemical impedance spectroscopy (EIS) tests were performed to evaluate the reaction kinetics during the HER and OER processes. The corresponding Nyquist plots and fitted results of the as-prepared catalysts were shown in Figure 5 and Table S4. The Electrolyte resistance ($R_s$) of 1M KOH electrolyte in the fabricated electrochemical test system was about 1.3 $\Omega$. Compared with the Ni foam (74.80 and 9.82 $\Omega$), NiFe LDHs (38.03 and 3.36 $\Omega$) and Pt/NiFe LDHs (0.63 and 0.92 $\Omega$) electrodes. The current density started at 10 increased to 20, 30, 40, 50, and 100, then down to 50, 40, 30, 20, and 10 mA cm$^{-2}$ every 4 h.

**Figure 5.** The Nyquist plots and corresponding equivalent electric circuit model of Ni foam, NiFe LDHs, Ni$_x$Fe LDHs, Pt/NiFe LDHs, and Pt/Ni$_x$Fe LDHs electrodes for (a) HER and (b) OER at an overpotential of 100 and 300 mV, respectively, in 1 M KOH solution. (c) Polarization curves for overall water splitting system and the inset optical image of $O_2$ and $H_2$ generated on Pt/Ni$_x$Fe LDHs $\|$ Pt/Ni$_x$Fe LDHs, RuO$_2$ $\|$ 20% Pt/C, 20% Ir/C $\|$ 20% Pt/C and NF $\|$ NF as both anode and cathode, respectively. (d) Multi-current process of Pt/Ni$_x$Fe LDHs electrodes. The current density started at 10 increased to 20, 30, 40, 50, and 100, then down to 50, 40, 30, 20, and 10 mA cm$^{-2}$ every 4 h.
the defective Ni<sub>x</sub>Fe LDHs (17.93 and 1.63 Ω) and Pt/Ni<sub>x</sub>Fe LDHs (0.46 and 0.64 Ω) electrodes showed smaller charge transfer resistance (R<sub>ct</sub>), suggesting superior electron conductivity and faster charge transfer kinetics in both HER and OER process. Meanwhile, the smallest R<sub>ct</sub> value of Pt/Ni<sub>x</sub>Fe LDHs electrode demonstrating the enhanced reaction kinetics after tethering Pt NCs on Ni<sub>x</sub>Fe LDHs surface. These results further revealed that the introduction of Pt clusters and the manufacture of defective M(II) sites promoted electron transfer and ion diffusion in the electrocatalytic process.

The crystal structure and chemical properties of Pt/Ni<sub>x</sub>Fe LDHs electrode after long-term durability tests were further tracked by XRD, XPS, SEM, and TEM techniques. Although the accelerated degradation tests (ADTs) for HER, OER, and ORR might cause considerable damage to the nanosheets, the overall phase structure and elemental composition of Pt/Ni<sub>x</sub>Fe LDHs were retained after the long-term ADT tests (Figure S12a and b). For the HER stability test, no obvious changes in Ni 2p were observed before and after 5000 CVs cycles and the percentage of Ni<sup>3+</sup> remained at 37.0% (Figure S12c) close to the initial value of 37.1%. Moreover, the XPS spectrum of Pt 4f also maintained the metallic state Pt (Pt<sup>0</sup>) without serious oxidation peaks in the high binding energy (Figure S12d). These findings further confirmed the binder-free design and hierarchical structure of Pt/Ni<sub>x</sub>Fe LDHs electrode could effectively promote the diffusion of HER intermediates to prevent the passivation of active sites, thereby maintaining the excellent electrocatalytic activity and long-term durability. For the OER stability analysis, as shown in Figure S12c, the content of Ni<sup>3+</sup> was raised to 39.7% compared with an initial 37.1%, the following DFT calculations revealed the increased defective sites reduce the adsorption energy of OER intermediates (Figure S19), thus leading to the decreased electrocatalytic overpotential (Figure S9d). The Pt 4f XPS spectra exhibited a predominantly high active metallic state (Pt<sup>0</sup>) accompanied with incremental oxidation state ratios (Pt<sup>4+</sup>) in high binding energy (Figure S12d), which was attributed to the surface oxidation under high potential in the OER process. Similar results were observed in Pt/Ni<sub>x</sub>Fe LDHs electrode after long-term ORR stability test, the slight oxidation of Pt caused by chemisorption of surface oxygenated species (Figure S12c and d). This further emphasized the metallic state of Pt with high catalytic activity cloud maintain during the process of reversible oxygen electrocatalysis. Moreover, the morphology Pt/Ni<sub>x</sub>Fe LDHs electrode after long-term durability tests were also investigated. As given in Figure S13, the interconnected nanosheets structure remains unchanged and Pt NCs attached on Ni<sub>x</sub>Fe LDHs nanosheets without obvious detachment or aggregation, suggesting splendid mechanical and electrocatalytic stability. In brief, all the data indicated the outstanding catalytic activity and long-term stability of the Pt/Ni<sub>x</sub>Fe LDHs electrode for HER, OER, and ORR.
The outstanding HER and OER performances of the Pt/Ni,Fe LDHs make it a promising bifunctional electrocatalyst for overall water splitting. A WAE was built by using Pt/Ni,Fe LDHs on Ni foam as cathode and anode, respectively (Figure S14a). As shown in Figure 5c, the Pt/Ni,Fe LDHs \(\parallel\) Pt/Ni,Fe LDHs electrolyzer yielded a current density of 10 mA cm\(^{-2}\) at 1.47 V, corresponding to an overpotential of 240 mV for overall water splitting. This value was much lower than that of the commercial catalyst 20% Ir/C \(\parallel\) 20% Pt/C (1.59 V, 360 mV), RuO\(_2\) \(\parallel\) 20% Pt/C (1.62 V, 390 mV) electrodes and recently reported transition metal-based bifunctional electrocatalysts for overall water splitting (Table S5). Vigorous hydrogen and oxygen bubbles were observed at both cathode and anode, respectively, during the overall water splitting process, as given in the inset photograph of Figure 5c. Moreover, the Pt/Ni,Fe LDHs \(\parallel\) Pt/Ni,Fe LDHs couple maintained excellent stability under various current densities in a chronoamperometric test for 44 h continuous operations (Figure 5d). Upon increasing the current density from 10 to 100 mA cm\(^{-2}\), the cell voltage increased accordingly and quickly became stable at each step, and delivered similar potentials change with the above OER chronoamperometric test in the reverse process. The observation was in good coincident with the enhanced OER performance caused by exposed more Ni\(^{3+}\) sites in long term alkaline soaking and further supported by the enhanced catalytic performance obtained after the stability test (Figure S14b). Additionally, the morphology of Pt/Ni,Fe LDHs kept well on both cathode and anode after the durability test (Figure S14c, d). Therefore, the Pt/Ni,Fe LDHs unfolded a high performance of overall water splitting with excellent bifunctional electrocatalytic activity and stability.

![Figure 6. Atomic structure of Pt atom bonding with (a) Fe site and (b) Ni site in NiZnFe LDHs.](image)

Several significant parameters such as deposition time, potential, temperature, base-etching time, and different metal proportions, which might influence the catalytic
activity were also investigated. By contrast, the HER catalytic activity and $C_{dl}$ of Pt/Ni$_x$Fe LDHs initially increased along with the prolonged deposition time and achieved a maximum value at 300 s (Figure S15a, b). However, the $C_{dl}$ decreased significantly with the further extending deposition time. The results exhibited that excessive LDHs and Pt NCs loading would decrease the electrochemical surface area and catalytic efficiency. Moreover, the HER performance and $C_{dl}$ investigation of electrochemical deposition potential (Figure S15c, d), temperature (Figure S15e, f), and base-etching time (Figure S15g, h) were in good agreement with before SEM morphology characterization, further verified the optimized experimental condition for obtained Pt/Ni$_x$Fe LDHs with high electrocatalytic activity and good morphology.

Notably, the electrocatalytic performances of Pt/Ni$_x$Fe LDHs electrodes were enhanced significantly after Fe elements incorporation into the NiZn(OH)$_x$ lattice, as shown in Figure S16. The introduction of Fe to LDHs matrix not only improved the oral conductivity and but also promoted the electrons transfer to adsorbed reactants due to the highly dispersed FeO$_6$ octahedra.\textsuperscript{34, 35} Moreover, the positively charged Fe$^{3+}$ in the LDH matrix also acted as stronger bonding sites to immobilize Pt NCs, which was further verified by the DFT calculation (Figure 6). The adsorption energy of Pt NCs via the Fe$^{3+}$-O(H)-Pt bonding was -4.87 eV, which was lower than that of Ni$^{2+}$-O(H)-Pt bonding (-4.61 eV), suggesting the strong interaction of Pt NCs with site-specific Ni$_x$Fe LDH sheets, which was consistent with previous studies.\textsuperscript{16} Therefore, the Pt/Ni$_x$Fe LDHs electrode displayed remarkably catalytic stability compared with that absence of Fe precursor (Figure S16d). The observed slopes indicated that the ECSA was increased obviously after introducing a small amount of Fe elements while excessive usage led to negative effects (Figure S16e), which was agreed well with the electrocatalytic performance. The effects of different Ni/Zn molar ratios on the catalytic performance were also investigated by maintained the usage of Fe and Pt precursor unchanged. As given in Figure S17, appropriate Ni/Zn ratios in Pt/Ni$_x$Fe LDHs matrix could decrease the initial potential and overpotential, and even achieved an extremely large current density under high potential. Compared with others, Pt/Ni$_x$Fe LDHs (Ni to Zn is 9:1) exhibited not only decent trifunctional catalytic properties but also enlarged ECSA which can provide more active sites (Figure S17d). Moreover, in the present method, the amount of Pt precursor was another key factor for the formation of high-performance catalysts. Figure S18 revealed that the trifunctional catalytic properties were enhanced significantly after tethering Pt NCs on the defective Ni$_x$Fe LDHs surface. The catalytic performance was linearly correlated with the addition of the Pt precursor, while the ECSA was decreasing with the continuous increased usage of Pt precursor (Figure S18d). This may be attributed to the high amount of Pt precursor induced the aggregation of Pt NCs on the surface of Ni$_x$Fe LDHs, as shown in Figure S6, thus
resulting in the decreasing of active sites and unsatisfied electrocatalytic performance. The above results further illustrated the flexibility and expansibility of the developed electrosynthesis method, as well as the controllable adjustment of the catalytic properties.

Figure 7. (a) Optimized model structures of H$_2$O, H$_2$O dissociation, *H, and *OH intermediates adsorbed on Pt/Ni$_x$Fe LDHs and Pt/NiZnFe LDHs surfaces. (b) Calculated adsorption energy diagrams for H$_2$ desorption; (c) adsorption energies of *O, *OOH, and O$_2$ on Pt/Ni$_x$Fe LDHs and Pt/NiZnFe LDHs surfaces.

DFT calculations were further performed to investigate the inherent relationship between the electronic structure and the outstanding electrocatalytic HER/OER performance under alkaline conditions. In this study, to better describe the interatomic interactions, in our Ab initio calculations, we applied Pt atom, instead of Pt nanoparticle; however, we admitted that these nanoparticles are not atomically dispersed in practical applications. As shown in Figure 7a, the defective Pt/Ni$_x$Fe LDHs exhibited a lower water adsorption energy of -2.83 eV compared with Pt/NiZnFe LDHs, indicating an accelerated Volmer step. Based on the water-splitting reaction in alkaline media, the adsorption energy of activated H$_2$O, *H, and *OH intermediates were calculated on the Pt sites in NiZnFe LDHs and Ni$_x$Fe LDHs, respectively. As given in Figure 7a, the absorption energy of intermediates on Pt/Ni$_x$Fe LDHs was lower than that on the pristine Pt/NiZnFe LDHs, leading to more rapid H$_{ad}$ and hydroxyl adsorption and
Besides, Pt/Ni$_x$Fe LDHs presented weakened adsorption energy of H$_2$ (-1.24 eV) compared to Pt/NiZnFe LDHs (-1.17 eV), demonstrating that the generated H$_2$ on the Pt/Ni$_x$Fe LDHs surface were more easily desorbed to avoid accumulation, thus facilitating the exposure of active sites and further accelerating the reaction process (Figure 7b). Moreover, the defective Pt/Ni$_x$Fe LDHs showed a similarly enhanced OER process with a low adsorption energy of *O and *OOH intermediates and superior desorption of O$_2$ (Figure 7c and S19). The above results further verified the manufactured M(II) defects on Pt/Ni$_x$Fe LDHs could effectively decrease the electrocatalytic reaction barrier and enhance reaction kinetics by adjusting the electronic structure of surrounding active sites, thereby achieving highly efficient water splitting performance, which was in good agreement with our experimental findings (ie. XPS, LSVs and EIS).

Based on the above studies, we propose the following discussions which may explain the excellent electrocatalytic activity of the Pt/Ni$_x$Fe LDHs catalyst: (1) the unique layered structure of LDHs with large surface areas could provide sufficient electroactive sites and stronger bonding sites to immobilize Pt NCs (via the Fe$^{3+}$-O(H)-Pt bonding). (2) the in-situ growth of sub-nm Pt NCs improves the electrical conductivity of LDHs and accelerates the electrocatalytic kinetic process. (3) the intimate contact between Pt NCs with LDHs forms profitably synergic effects, which could facilitate the dissociation of H$_{ad}$ and recombine into molecular hydrogen. (4) the introduction of M(II) vacancies tunes the surface electronic structure, optimizes the adsorption of O intermediates, promotes the evolution of O$_2$. (5) the overall hierarchical porous architecture enables good mechanical adhesion, promotes fast electron/mass transport and rapid gas bubble dissipation. Furthermore, the Pt/Ni$_x$Fe LDHs catalyst was directly deposited on conductive substrates to fabricate 3D freestanding electrodes in the absence of binder or capping additives, enhancing the intrinsic electrocatalytic activity of active sites. Thus, the above intriguing merits undoubtedly make Pt/Ni$_x$Fe LDHs a binderless, bifunctional, and high-performing catalyst in the overall electrochemical water splitting system.
2.3. ORR and HSABs performance.

Figure 8. (a) ORR/OER bifunctional LSV curves of Pt/Ni$_x$Fe LDHs and NiFe LDHs. (b) Open-circuit voltage plots, (c) charge-discharge voltage curves, (d) discharge voltage curves under from 0.01 increased to 0.02, 0.03, 0.04, 0.05 then reversed to 0.01 mA cm$^{-2}$ every 30 mins, and (e) cycling tests of HASBs with different electrocatalysts at air cathode. (f) The terminal voltages, overpotential gap ($\Delta V$), and roundtrip efficiency during cycling of HSABs using Pt/Ni$_x$Fe LDHs.

Apart from the excellent HER activity, Pt-based material was also considered as the best of ORR catalysts.$^{39-41}$ Therefore, the ORR catalytic activities of Pt/Ni$_x$Fe LDHs were also investigated in 0.1 M $\text{O}_2$-saturated KOH electrolyte. As shown in Figure 8a, Pt/Ni$_x$Fe LDHs exhibited a catalytic ORR peak with a high half-wave potential ($E_{1/2}$) of 0.87 V, while no obvious ORR signal was observed for the compared NiFe LDHs catalyst, suggesting the improved ORR activity by immobilization of Pt NCs on LDHs.
nanosheet. The peaks around 1.3-1.4 were ascribed to the reduction of Ni$^{3+}$ ions. The potential difference between $E_{j=10}$ (the potential required for generating a current density of 10 mA cm$^{-2}$ for OER) and $E_{1/2}$ (noted as $\Delta E = E_{j=10} - E_{1/2}$) was calculated to evaluate the bifunctional catalytic activities toward OER and ORR (Figure 8a). Notably, the reversible oxygen overpotential of Pt/Ni$_x$Fe LDHs was 0.72 V, lower than recently reported bifunctional electrocatalysts (Table S6). The remarkable OER and ORR bifunctional electrocatalytic activity and self-supporting features of Pt/Ni$_x$Fe LDHs made it an appealing air electrode material for rechargeable metal-air batteries and fuel cells.

As one of the promising next-generation batteries, hybrid Na-air batteries (HSABs) are received considerable attention owing to their high specific capacity (838 mAh g$^{-1}$), higher theoretical standard cell voltage (3.11 V), and low cost. Strikingly, the HSAB fabricated with Pt/Ni$_x$Fe LDHs air cathode exhibited a stable open-circuit voltage of 3.01 V, which was almost near the standard voltage of 3.11 V, higher than that of referential battery with 20% Pt/C+20% Ir/C (2.95 V) and RuO$_2$ (2.83 V) as the cathode (Figure 8b), suggesting its preeminent ORR performance. It is widely known that the sluggish kinetics of OER/ORR processes on the cathode side is the main reason for the large voltage gap ($\Delta V$). In contrast, the battery using the Pt/Ni$_x$Fe LDHs delivered a stable charge/discharge plateau (2.93/3.34 V) with a narrow $\Delta V$ of 0.41 V and high round trip efficiency of 87.7%, suggesting the superior bifunctional OER and ORR catalytic performance on air electrode (Figure 8c). Figure 8d shown the discharge curves of HSABs using different air cathodes at various current densities. Compared to benchmark commercial catalysts, Pt/Ni$_x$Fe LDHs based-HSAB exhibited relatively linear and steady discharge performance, indicating good ORR performance and excellent stability benefited from the freestanding electrode structure. Moreover, the favourable stability of Pt/Ni$_x$Fe LDHs was further validated by cycling tests, no stark polarization observed in the initial 50 cycles (Figure 8e), while the 20% Pt/C+20% Ir/C and RuO$_2$-based battery failed less than 30 cycles, indicating good rechargeability of Pt/Ni$_x$Fe LDHs based-battery. Dramatically, the Pt/Ni$_x$Fe LDHs-based battery achieved long-term cycling over 1000 cycles under a current density of 0.01 mA cm$^{-2}$ with 10 min discharge/charge (Figure S20), corresponding with an average charge/discharge voltage of $\sim$3.39/$\sim$2.73 V, a small voltage drop of $\sim$0.66 V and high round trip efficiency of $\sim$80.6 % (Figure 8f), significantly surpassing the previously reported HSABs (Table S7). Besides, the negligible change of morphology after the long-term durability test further elucidated the excellent cycling stability (inset in Figure S20).

Generally, the superior performance and remarkable rechargeability of Pt/Ni$_x$Fe LDHs based air cathode might be ascribed to the following features: (1) the enhanced kinetic synergy between M(II) vacancies and Pt NCs on nanosheet surface, which
minimizes the potential difference between OER and ORR in alkaline medium. (2) the hierarchically porous architecture enables high accessibility for electroactive sites, rapid mass transfer, and inhibits the accumulation of cycling-derived byproducts. (3) the binder-free design possesses more exposed active sites, resulting in superior electrode performance. (4) the Pt/Ni,Fe LDHs vertically grown on 3D Ni foam ensures high electroconductivity and good structure stability.

3. CONCLUSIONS

In summary, a facile, effective electrochemical deposition strategy was proposed to prepare binder-free, high-performance electrodes for HER/OER/ORR. Sub-nm Pt NCs \textit{in-situ} decorated on defects-rich Ni\textsubscript{x}Fe LDHs nanosheets on Ni foam electrodes were prepared without using any capping reagents. M(II) vacancies in Ni\textsubscript{x}Fe LDHs nanosheets were generated from dissolving Zn sites in LDHs nanosheets, offering abundant coordinatively unsaturated active sites to absorb oxygen intermediates. The synergistic effects between abundant M(II) vacancies and sub-nm Pt NCs on LDH substrate, along with the hierarchically porous architecture, enhance the dissociation of H\textsubscript{ad} and optimize the adsorption of O intermediates, which greatly promotes the overall water splitting process. Moreover, the Pt/Ni\textsubscript{x}Fe LDHs electrode shows good electrocatalytic activities with a reversible oxygen overpotential of 0.72 V in alkaline electrolytes. Using Pt/Ni\textsubscript{x}Fe LDHs as a binder-free cathode in the HSAB, it delivers a high open-circuit voltage of 3.01 V with a narrow voltage gap of 0.41 V, excellent cycling stability and rechargeability over 1000 cycles compared to the mixed commercial catalysts. It is anticipated that this facile and scalable strategy of preparation of binder-free, high-performance electrodes would provide new opportunities to exploit future multifunctional electrocatalysts for practical sustainable energy conversion and storage technologies.

4. EXPERIMENTAL SECTION

4.1. Synthesis of Pt/NiZnFe LDHs, Pt/NiFe LDHs, NiZnFe LDHs, and NiFe LDHs.

Pt/NiZnFe LDHs were prepared by a facile electrodeposition method. Typically, Ni foam (10*20*0.05 mm\textsuperscript{3}) was treated with 3M HCl ultrasonicated for 15 min, then washed with water and ethanol to obtain a clean surface. The electrodeposition was conducted in a standard three-electrode system cell, well-cleaned Ni foam as the working electrode, Pt plate as the counter electrode, and Ag/AgCl (3 M KCl) as the reference electrode, respectively. The Pt/NiZnFe LDHs were synthesized in an electrolyte containing NiSO\textsubscript{4}·6H\textsubscript{2}O (0.027 M), ZnSO\textsubscript{4}·7H\textsubscript{2}O (0.003 M), FeSO\textsubscript{4}·7H\textsubscript{2}O (0.01 M), and K\textsubscript{2}PtCl\textsubscript{6} (0.002 M). The potentiostatic deposition was carried out at -1.0
V (vs. AgCl) for 300 s at room temperature. The obtained Pt/NiZnFe LDHs was rinsed carefully by water and ethanol, then left dried overnight in a vacuum oven. By replacing NiSO\textsubscript{4}·6H\textsubscript{2}O (0.027 M) and ZnSO\textsubscript{4}·7H\textsubscript{2}O (0.003 M) with NiSO\textsubscript{4}·6H\textsubscript{2}O (0.03 M) obtained the Pt/NiFe LDHs. For NiZnFe LDHs, the electrolyte was prepared similarly as Pt/NiZnFe LDHs except removed the Pt precursor. For NiFe LDHs, the electrolyte was the same as NiFe LDHs except for Pt/NiFe LDHs except removed the Pt precursor. The rest electrosynthesis process was the same as the above.

4.2. Synthesis of Pt/Ni\textsubscript{x}Fe LDHs, Ni\textsubscript{x}Fe LDHs

The introduction of Ni\textsuperscript{2+} vacancies in Pt/NiZnFe LDHs nanosheets or NiZnFe LDHs has followed the reported method with slight modification.\textsuperscript{12} Briefly, the as-prepared Pt/NiZnFe LDHs or NiZnFe LDHs were treated with 5 M NaOH for 2.5 h at room temperature. The obtained product was washed with water and ethanol at least three times and then dried overnight. The Pt/Ni\textsubscript{x}Fe LDHs or Ni\textsubscript{x}Fe LDHs nanosheets were synthesized.

4.3. Electrochemical measurements

Electrochemical measurements were performed with a three-electrode system using a CH760E electrochemical workstation at room temperature. The obtained electrocatalysts on Ni Foam (1*1 cm\textsuperscript{2}) were used as the working electrode, a platinum plate, and an Ag/AgCl (3M KCl) electrode was used as the counter and the reference electrode, respectively. All potentials measured were calibrated versus the reversible hydrogen electrode (RHE). HER and OER were investigated in 1 M KOH electrolyte, while the ORR test was studied in an O\textsubscript{2}-saturated 0.1 M KOH aqueous solution. The linear sweep voltammograms (LSVs) were recorded at a scanning rate of 10 mV s\textsuperscript{-1} without \textit{iR} compensation. For more details see the Supporting Information.

4.5. Assembly and test of HSABs

The hybrid Na-air battery was fabricated in a sandwich structure using ceramic solid electrolyte NASICON with the composition of Na\textsubscript{3}Zr\textsubscript{2}Si\textsubscript{2}PO\textsubscript{12} having a high ionic conductivity of 8.9 × 10\textsuperscript{-4} S cm\textsuperscript{-1} at room temperature as a separator. Briefly, the anode compartment was assembled in the glove box. The metallic sodium plate was first placed into the chamber as the anode, followed by adding organic electrolyte (1 M NaClO\textsubscript{4} in tetraethylene glycol dimethyl ether). NASICON solid electrolyte was selected to seal the anode part to ensure that one side was in contact with the organic electrolyte and the other side was exposed to air. The as-prepared air electrode was directly immersed in the O\textsubscript{2}-saturated 0.1 M NaOH electrolyte under ambient air as the

ACS Paragon Plus Environment
The as-prepared simples on Ni foam (diameter 10 mm) were directly used as the air cathodes. By contrast, the 20% Pt/C+20% Ir/C and RuO$_2$ catalyst were coated on Ni foam (diameter 10 mm) with the mass loading of 1 mg cm$^{-2}$, respectively.

Battery tests were performed at room temperature by LAND test station (CT2001 A, Wuhan LAND electronics). Cycling performance was recorded at recurrent galvanostatic pulses for 5 min of discharge followed by 5 min charge.

4.6. Theoretical Calculations

All the calculations were conducted within Viena Ab initio Simulation Package (VASP),$^{45, 46}$ and the structure optimization was based on density functional theory (DFT). The modeling of exchange-correlation energy was performed with the implemented generalized gradient approximation (GGA), proposed by Perdew-Burke-Emzerhof (PBE).$^{47, 48}$ The valence electronic states were expanded with the plane waves; and the core-valence interactions were described using the projector augmented wave (PAW) approach,$^{49}$ with the corresponding cutoff kinetic energies set to 450 eV. For our simulated systems, the total number of atoms is larger than 160, thus the Brillouin zone was set with a Gamma-centered k-point grid of 1x1x1.$^{50}$ And, to further improve the convergence of the simulated systems, a Gaussian functionalized Fermi surface, with a broadening magnitude of 0.1 eV was used. The structures were first relaxed with the implemented conjugate-gradient algorithm, until the convergence tolerance of Hellmann-Feynman forces and energy on each atom was less than 0.02 eV/Å and $10^{-4}$ eV/atom, respectively. Moreover, due to the periodic boundary conditions (PBC), there exist non-negligible interactions among periodical images; to reasonably overcome this, a separate vacuum layer, with a thickness of 15 Å along the z-direction, was applied. Also, for all the calculations, spin polarization was considered. Since we merely focus on the relative energies of concrete reactions rather than the band gaps, we didn’t introduce DFT + U corrections into our Ab initio calculations in this study.
